INDEX.

Abdominal diseases of women, 1.
pulsation, 942.
Abortions and the use of strychnine, 75.
Acclimatization, problem of, 676.
Acetonuria, 314.
Acne indurata, 604.
Aconitia, oleate of, 45.
Act to establish a State Board of Health, 557.
Actinomycosis in Chicago, 362.
Addison's disease, case of, 454.
Adulteration of food and drugs, recent legislation on, 566.
Agnew, D. H., a case of nephrorrhaphy and nephrectomy, 708.
Agraphia, 502.
Air-embolism, 625.
Alcohol habit, new treatment of, 738.
Alcohol, moderate drinking of, 74.
substitutes for, 915.
Alexander's operation for retroversion of the uterus, 857.
Alopecia, 682.
Ammonia and alcohol for snake-bite, 928.
Amygdalotomy, 878.
Anæmia, discussion on, 633.
three cases of idiopathic, 601.
Anæsthetic, cannabis indica as a local, 641.
Anæsthetics in labor, 821.
Angina pectoris, diet for, 289.
Antipyrine, 551.
Antiseptic, trichloracetic acid as an, 728
Antiseptic inhalations, 696.
Aortic aneurism, laparotomy for, 600.
Aphasia, sensory, 178.
Apomorphine in asthma, 389.
Army and Navy Changes: 36, 76, 112, 148, 184, 220, 260, 296, 336, 372, 408, 448, 484, 520, 560, 600, 636, 672, 712, 748, 784, 820, 856, 892, 928, 964.
Arsenic in chloride of lime and chlorate of potash, 961.
Arteries, healing of, after ligature, 623.
Artery-compressor, 23.
Aseptol, 774.
Asthma, apomorphine in, 389.
pyridine in, 836.
treated by pyridine, 774.
Astigmatism and sick-headache, 371.
Astragalus, resection of, 182.
Atlee, W. F., on dermoid cyst, 675.

Barbasco, 483.
Barton, J. M., removal of uterus and ovaries, 316.
Baths in acute pneumonia, 320.
Baum, Charles, statistics of nephrectomy, 381.
Bayberry tallow as an embedding medium, 631.
Bennett, Charles D., sarcoma of peritoneum, 425.
Bernardy, E. R., biniodide of mercury, 953.
gestation in sarcomatous uterus, 956.
Blackwood, W. R. D., report on electricity, 159, 570.
Blepharitis marginalis, 185.
Blistering, danger of, 606.
Board of health, powers of, 712.
Boenning, H. C., on cocaine, 274.
Boldo, 540.
Bosworth, F. P., on the three tonsils, etc., 105.
Brain, arterial embolism of, 149.
bullet-wound of, with recovery, 146.
compressibility of, 205.
locomotion of, 874.
surgery, 585.
Brain-abscess with double optic neuritis, 195.
Breast-amputation, after treatment of, 393.
Bromoform, bromethyl, and bromethyline, 46.
Bronchitis in children, 221.
Broncho pneumonia, pathology of, 153.
Brose, L. D., compound fracture of the skull, 902.
Brucine in ear-diseases, 817.
Bruen, E. T., on parenchymatous inflammation of the liver, 561.
on pericarditis, 261.
Burchard, T. H., on medical and surgical treatment of acute peritonitis, 745.
Burnett, Charles H., report on progress of otology, 39, 87, 345, 384, 826.
Byford, William H., on mural pregnancy, 331

Calculus, impacted renal, 276.
Cancer of liver, primary, 666.
Cannibalism, criminality of, 75.
Carbon bisulphide as a disinfectant, 18.
Carbonic-oxide poisoning, 97.
Carcinoma, general, 138.
Caries, nil desperandum in spinal, 739.
Castle, F. D., on ophthalmology, 704.
Cataract, diagnosis of incipient, 705.
operation, 610.
Celluloidin for microscopic work, 810.
Cerebellum, pathology of, 745.
Cerebral hemispheres, functional independence of, 90.
infantile paralysis, 926.
Cervical pregnancy, 474.
Chancre, ten cases of extra-genital, 80.
Chancroid, diagnosis of, 908.
Charcot's joints, six cases of, 528.
Chests, examination of weak, 705.
Cholecystotomy, 626.
Cholera at Suspension Bridge, 179.
commissions and their lessons, 482.
etiology of, 818.
Ferran's inoculations, 804.
germs, 34.
in Spain, 784.
precautions, 371.
prevention, 519.
report on means of preventing spread of, 405.
the cause of, 144.
use of caffeine in, 204.
vaccinia, 557.
Chorea, has it an essential lesion? 770.
treatment of, 771.
Christine, G. Maxwell, case of hemorrhage fatal to mother and child, 199.
Chrysarobin solution for ringworm, 600.
Chyluria, 278.
Coal-gas, dangers from, 450.
Coca in fatigue, 446.
wine for invalid travellers, 635.
Cocaine hydrochlorate, 91, 274.
disks, 350.
for sore nipples, 688.
in dentistry, 220.
in ear-diseases, 817.
in melancholia, 745.
in purpura hæmorrhagica, 380.
Coca-leaf cigars, 933.
Cohen, S. Solis, on acute coryza, 835.
Colotomy, new method of, 611.
Comedones, 110.
Comma-bacillus, 369.
Constipation treated by ergot, 235.
Consumptives, sea-voyages for, 874.
Convallamarin, 519.
Conversazione at College of Physicians, 600.
Convulsions due to constipation, 293.
Coryza, notes on treatment of acute, 835.
Counter-prescribing in France, 47.
Cremation societies, 856.
Croup, discussion on, 209.
tracheotomy for, 285.
treated by fumigations, 837.
Cunningham, T. A., sprain of ankle-joint treated by rest and compression, 904.
Curare, inutility of, in epilepsy, 837.
Curtin, Roland G., pernicious anæmia, 494.

Da Costa, J. M., clinical remarks on post-typhoid elevation of temperature, 236.
remarks on clinical cases, 149.
Dead, disposal of the, 100.
Decapitation, experiments after, 691.
Degeneration, reactions of, 337.
Delafield, Francis, on broncho-pneumonia, 153.
on emphysema and empyema, 373.
Dermatitis bullosa, hereditary, 680.
herpetiformis, 936.
Dermatology, report on progress of, 420, 645, 678, 936.
Dermoid cyst discharging into intestine, 675.
cysts, origin of, 652.
Diabetes mellitus, pathology of, 782.
tendon reflexes in, 309.
treatment of, 945.
Diagnosis of thoracic disease, 497.
Diphtheria, carbolic-acid inhalations in, 390.
new remedies for, 394.
open-air treatment of, 781.
treatment of, 237, 803, 810.
Diuretics as therapeutic agents, 860.
Double uterus and vagina, 403.
Doundakine, 394.
Drainage-question in Philadelphia, 713.
Draper, W. H., on antipyrine, 551.
Drowning, self-inflation in, 335.
Dyspepsia and acid remedies, 356.
Austin Flint on, 323.
Dystocia, cervical fibroids as a cause of, 62.

Ear, syphilis of, 345.
Eczema, 682.
of genitals, 540.
of scalp, 47.
treatment of, 878.
EDITORIALS AND LEADING ARTICLES:
Volume XV., 28.
Mycology in old clothes, 28.
Tea and coffee, 48.
Professor William Osler, 49.
Peculiarities of conformation in the skulls of criminals, 50.
State examining boards, 92.
A lesson from the Electrical Exhibition, 93.
Expert medical witnesses, 130.
Glosso-labial paralysis, 131.
Salt *vs.* snow in the streets, 131.
The lesions of locomotor ataxia, 165.
An appeal to Congress, 166.
The New York State Medical Association, 166.
Diabetes mellitus from a physiological stand-point, 206.
The labors of the Lunacy Board, 208.
A fatal endemic bowel-disorder in Virginia and Kentucky, 208.
The proposed act of the Legislature creating a State board of medical examiners and licensers, 238.
The need of legal control over medical practice, 239.
Are laws regulating the practice of medicine constitutional? 240.
1884–1885, 279.
The abuse of antipyretics, 280.
The coagulation of the blood, 321.
Comma-bacilli and cholera, 322.
Collective investigation, 322.
State Board of Health, 323.
Trephining the skull for a growth in the brain, 357.
The insane department of the Philadelphia Hospital, 358.
Internal urticaria, 358.
Æsthetic orchidectomy, 358.
Overwork and neurasthenia, 391.
A new hospital wanted, 392.
The state of the cortical motor centres in epilepsy, 431.
Idiopathic anæmia of Addison, 464.
Ergot, 465.
The case of General Grant, 466.
Shall the American Medical Association be reorganized? 541.
Public health notes, 542.
Annual meetings of the Medical and Surgical Associations, 575.
A Pennsylvania typhoid outbreak, 576.
Nervous symptoms of enteric fever, 577.
The American Medical Association and the committee on the International Medical Congress, 607.
Virchow and his *Archiv*, 608.
The American medical profession and the proposed International Congress, 653.
The Plymouth outbreak.—A State Board of Health wanted, 654.
Æsthetics in a new relation, 684.
Transactions of societies, 684.
An invitation to the cholera, 685.
The State Board of Health, 685.
Summer-resorts for the sick poor, 729.
Professor Henle, 730.
The disposal of sewage, 730.
Hot-weather hygiene, 768.
The International Medical Congress and the profession, 768.
Members by application in the American Medical Association, 769.
Has chorea an essential lesion? 769.
Exit Peronospora Ferrani, 802.
The prophylactic treatment of blennorrhœa neonatorum, 802.
Alumni Association prize, 802.

EDITORIALS AND LEADING ARTICLES.—*Continued.*
Journalistic change, 838.
Bacteria as therapeutic agents, 838.
The attitude of the medical profession towards criminals, 875.
Some results of public health work, 876
Legal status of medical works in court, 876.
Indirect causes of summer diarrhœa in infancy, 909.
The new building for the National Medical Museum and Library, 910.
The operative treatment of intestinal obstruction, 946.
The work of the Committee on Organization of the International Medical Congress, 947.
Electric lamp, 199.
Electrolysis in dermatological practice, 832.
Elsberg, Louis, lecture on classification of laryngeal neuroses, 37.
Emphysema and empyema, 373.
Empyema, 373.
Endocarditis, ulcerative, 140.
Endometritis exfoliativa, case of, 900.
fungosa, 664.
Engel, Hugo, infectious sore throat, 225.
lecture on arterial embolism of the brain, 749.
on epilepsy, 409.
English Cholera Commission, 34.
Enteritis caused by corrosive-sublimate dressings, 801.
Epilepsy, 126.
lecture on, 409.
removal of uterine appendages for, 174.
treatment of, 327.
Epithelioma, results of operative treatment for, 500.
Ergot, action of, 356.
for hiccough, 908.
Erysipelas and antisepticism, 543.
of larynx and pharynx, 813.
treated with pilocarpine, 151.
Erythromelalgia, 288.
Ether, death from, 75, 779.
Ether-inhalation apparatus, 627.
Expert and non-expert evidence, 162.
Eye, hysterical affections of, 642.
surgery, antiseptic, 613.

Fibro-sarcoma, naso-pharyngeal, 108.
Fisher, H. F., typhoid fever complicated with tetanus, 673.
Flint, Austin, on dyspepsia, 323.
Florida, climate of, 699.
Fœtus, signs of death of, 163.
Foreign body in the eye, 271.
Fothergill, J. M., London letter, 29, 95, 167, 282, 359, 433, 505, 581, 655, 731, 839, 910.
Fracture of humerus, 904.
Friedreich's disease, 745, 758.
Fullerton, Anna M., letter by, 35.

Gall-stone, 508.
Galvanism for intestinal occlusion, 393.
in chronic diseases of the pharynx, 812.
Gangrenous uterine fibroma, 599.
Gastralgia, 127.
Gastric ulcer, 348.
Gastritis favosa, 291.
Gastrotomy for hair tumor, 164.
Gaultheria in acute rheumatism, 320.
German Hospital, gift to, 182.
Gibney, V. P., comparative results of treatment in chronic osteitis of the hip, 190.
Gihon, Albert L., trade-aspect of medicine, 116.
Glaucoma and homatropin, 278.
from homatropin, 196.
iridectomy under cocaine, 354.
Glycerin treatment of trichinosis, 945.
Goitre, exophthalmic, 497.
Goodell, William, year's work in laparotomy, 516.
on rapid dilatation of the uterine canal, 265.
Grant, malady of General, 559.
Greene, William H., report on medical chemistry, 122, 313, 531.
Gumma of the auricle, 42.

Hæmatoma auris, 39.
Hare, H. A., action of sulphate of quinia upon the blood, 43.
Harris, H. C., on paraldehyde, 602.
Head, gunshot wounds of, 632.
Heart, irritable, 394.
Hemicrania, sodium salicylate for, 406.
Hepatic disease statistics, 759, 863.
Hernia, radical treatment of, 890.
treatment of, 329.
Herpes zoster, 278.
bilateral, 938.
treated by salicylate of sodium, 801.
Heyl, A. G., oleate of aconitia in ophthalmic practice, 45.
report on ophthalmology, 195, 490, 795.
Hip, chronic osteitis of, 190.
Holland, J. D., our personal equations, 521.
Hollopeter, W. C., inverse type of temperature in typhoid, 304.
Homatropin and glaucoma, 278.
Hopkins, W. Barton, apparatus, 508.
HOSPITAL NOTES:
Hospital College of Medicine, Louisville, Kentucky.
Dudley S. Reynolds, M.D., 351.
Hospital of the University of Pennsylvania.
William Pepper, M.D., 126, 275.
John Ashhurst, Jr., M.D., 389, 460.
Jefferson Medical College Hospital.
J. M. Barton, M.D., 904.
Medico-Chirurgical Hospital.
James E. Garretson, M.D., 23.
William F. Waugh, M.D., 942.
New York Hospital.
George L. Peabody, M.D., 496.
L. D. Bulkley, M.D., 603.
Pennsylvania Hospital.
J. M. Da Costa, M.D., 236.
Thomas G. Morton, M.D., 318.
Philadelphia Hospital.
Charles K. Mills, M.D., 534, 648.
J. M. Keating, M.D., 799.
Hot water, therapeutical applications, 136.
Humerus, compound complicated fracture of, 318.
Hutchinson, J. M., note on kairin, 157.
Hydatids in the urine, 887.
Hydrocele, chylous, 278.
in women, 205.
Hyperpyrexia treated by cold affusions to the abdomen, 149.
Hysterectomy, 316.
for uterine cancer, 47, 65.
Hysteria, aural symptoms, 347.
Hystero-epilepsy in the male, 648.

Index Medicus, 504.
Inebriety, contagiousness of, 292.
Infant-feeding, 958.
Infants, surgical treatment of, 785.
Influenza, pathology of, 19.
Insane asylum burned, 336.
Intermittent fever, inoculation for, 925.
International Medical Congress, 293, 962.
Intestinal catarrh, 275.
obstruction, 260.
fatal, 109.
Intussusception, intestinal, 632.
Iodoform, eczema due to, 390.
for laryngeal ulcer, 129.
Iritis serosa of syphilitic origin, 796.
syphilitic, 640.
Irritable spine, 293.
Irwin, J. A., effects of sea-voyaging, etc., 628.

Jackson, Edward, examination of applicants for license to practise, 85.
on diagnosis of cataract, 703.
Jacksonian epilepsy, 370.
Jacobi, A., address by, 401.
Jaundice from arsenical wall-paper, 783.
Jequirity in skin-diseases, 147.
microzymes of, 962.
July weather, 856.

Kairin, note on, 157.
and antipyrine, 394.
Kearns, W. D., improvement in splints for fracture of forearm, 740.
Keating, John M., lecture on subacute bronchitis in children, 221.
on infant-feeding, 958.
on spasmodic tabes dorsalis, 376.
Keloid, extensive, 318.
tumors, 773.
Keratin-coated pills, 961.
Keratitis, syphilitic, 351.
Keyser, Peter D., relation of the medical colleges to preliminary education, 202.
Kidney-disease, with epithelioma uteri, 462.

Labor, remarks on management of, 309, 330.
Lactic acid in tubercular deposits, 874.
Landesberg, M., foreign body in the eye, 271.
Laparotomy, a year's work, 516.
exploratory, 4, 60.
foreign bodies in the abdomen after, 58.
Laryngeal neurosis, 37.
Larynx, extirpation of, 540.
respiratory function of, 812.
"Lawn tennis" back, 387.
Lead-poisoning, 150.
Lee, Benjamin, on spinal caries, 739.
Leffmann, Henry, report on hygiene, 454.
Legal control of medical practice by a State examination, 230.
Lepra bacilli, 605.
Leprosy in Baltimore, 842.
presence of bacilli in, 121.
Leucoplakia buccalis, 813.
Levis's artery-compressor, 23.
License to practise, 85, 230.
Linn, Thomas, Paris letter, 393, 466, 543, 609, 689, 770, 803, 877, 914, 948.
Liver, parenchymatous inflammation of, 561.
Lloyd, J. H., on reactions of degeneration, 337.
Loomis, A. L., address by, 694.
Lupus, 645.
cured by arsenic, 540.
treated by pyrogallic acid and mercurial plaster, 145.

Malarial poisoning, influence of, on pregnant women, 940.
Maltine, 820.
Massey, G. B., report on neurology, 756.
Mastoid, opening of, 204.
McIntire, Chas., Jr., "lawn tennis" back, 387.
Mears, J. Ewing, ether-inhalation apparatus, 627.
phosphor-necrosis, 627.
Medicinal eruptions, 681.
Medico-legal decisions, 334.
notes, 295.
Mercury, biniodide of, in obstetrics, 953.
ointment, a new way of making ammoniated, 682.
Micrococci in relation to wounds, abscesses, and septic processes, 143, 146.
Migraine, treatment of, 76.
Mills, C. K., a case of nymphomania, etc., 534.
hystero-epilepsy, 648.
Mistakes in dispensing drugs, 927.
Mittendorf, W. F., on blepharitis marginalis, 185.
Monoplegia in tubercular meningitis, 430.
Morbus maculosus Werlhofii, 320, 427.
Morphiomania, treatment of, 546.
Morton, Thos. G., two cases of dislocation of the tarsus, 452.
Musser, J. H., on hepatic disease, 759, 863.
on idiopathic anæmia, 601.
Myelitis, recovery after chronic, 742.
Myxœdema, pathology of, 259.

Nasal catarrh, pathology of, 479.
National Board of Health, 371.
Neoplastic diathesis, 33.
Nephrectomy, 258, 594, 613.
statistics, 381.
Nephritis in infancy, 959.
Nephrolithotomy, 596.
Nephrorrhaphy and nephrectomy, 708.
Nerve-stretching, 544
effects of, on the spinal cord, 927.
Neuralgia due to exostosis, 87.
osmic acid in, 743.
surgical treatment of, 23.
Neuroretinitis, 796.
New-born, blennorrhœa of the, 795.
New Jersey State Medical Society, annual meeting, 783
New York Medico-Legal Society, 520.
Notes and Queries:
Women students in Vienna, 35.
Treatment of migraine, 76.
Freiburg, 220.
Medicated tampons, 296.
An old form, 336.
Strapping the testicle, 448.
Morbus maculosus Werlhofii, 484.
Death of Dr. Joseph Klapp, resolutions on, 484.
Active principle of ergot, 520.
Rötheln, 636.
Paracentesis for ovarian disease, 784.
Vis medicatrix naturæ wanted, 892.
Treatment of diphtheria, 892.
A strange accident, 928.
Ammonia and alcohol in snake-bite, 928.
Nymphomania with hystero-epilepsy, 534.

Obituary Notices:

ORIGINAL LECTURES.

CLINICAL LECTURE ON SOME CASES OF ABDOMINAL DISEASE IN WOMEN.

BY MR. LAWSON TAIT.

(Reported for the *Philadelphia Medical Times*.*)

AT the Hospital of the Jefferson Medical College, on September 15, the day of the opening of the preliminary course of lectures, a large company of physicians and students were present, by invitation, to attend a clinical lecture by Mr. Lawson Tait, of Birmingham, England.

Professor Parvin introduced the lecturer in a few words, as one who needed no introduction to the most of those present.

Mr. Tait said:

I really do not know what Dr. Parvin has brought me here for, unless in his desire to show me attention he wishes to overwhelm me with kindness. I know that this is a tendency you have here, to overwhelm visitors with kindness, as it is sometimes in my own country. I have been told constantly since my arrival that I am in the country of big things; and now I find myself in the city of biggest things. I was, this morning, in the biggest store I ever saw, and to-day I ate the biggest oyster I ever ate in my life, and now I am in the biggest amphitheatre of any medical college anywhere. I know that we have nothing like it in England.

Now I am asked to do the biggest thing of all, and to lecture to you upon cases that I never saw until a few minutes ago, and examined only for about ten seconds each. Under these circumstances it is not unlikely that I may make some mistakes, and make a diagnosis which is incorrect; but if I do so I must ask you to pardon me, not because I am often given to making mistakes of this sort,—I hope I am not,—but because since I have been here I have been taken somewhat with the American disease, and am too much disposed to "hurry things."

Before bringing the cases before you, let me say a word upon the diagnosis of abdominal affections. It has been said that the most difficult thing in the world is a diagnosis in the belly. I am in the habit of illustrating this in a familiar way, in this manner: here is a table; it has a table-cloth on it. Now, I know that this is a table and table-cloth, but it is impossible for me to say what kind of wood is in the table until the cloth is removed. Just so is it with abdominal growths.

Now, it is just in this character of disorder that hurry is most likely to cause mistakes of a serious character. In no other department is a careful diagnosis more needed than in abdominal surgery; for you proceed immediately to perform an operation for its relief, and you are sure to be found out if you make a mistake.

A distinguished American physician told me the other day—and I shall not forget it—that a doctor may tell his patient that he has dulness here or râles there, and the patient moves off, and no one can tell whether he was right or not; but in abdominal surgery if we make a mistake we proceed to act at once upon the diagnosis by opening the abdomen. Therefore, on account of the obscurity of the case and the serious consequences of a mistake, you should act with the more caution in making up your opinion.

In proceeding to examine the patients brought before you, I will ask again that you bear in mind the necessity of careful and thorough investigation of the cases, and that, in consequence of my lack of opportunity to do this, I may make some mistakes: if I do so, and, upon subsequent examination, Dr. Parvin finds reason to correct any diagnosis that I may make this afternoon, you must pardon it.

REMARKS ON OVARIAN TUMOR, AND EARLY OPERATIONS FOR ITS RELIEF.

The patient who has just been brought in is suffering with a disease which is a very common one with us, and also, I have no doubt, quite common with you: it is said to be a case of ovarian tumor by those who have had her under their care.

Upon exposing the prominent abdomen and inspecting its surface, the first thing that strikes my eye is the scar of a puncture near the navel and on a level with it, and a second one a little lower down. These are the marks of two tappings of the abdomen, which were not ordered by any one here. Upon this I will speak further in a few minutes.

* Corrected by the author.

You notice that there is a symmetrical uniformity about this abdomen. Now, whenever you see a symmetrical enlargement of the abdomen, you should suspect that it is not due to an ovarian tumor. It is likely to be one of three things: (1) pregnancy, which you must always eliminate; (2) a small tumor, or malignant growth in the abdomen, accompanied by effusion of ascitic fluid; and (3) a parovarian tumor.

Let me give you a word of caution just here: when you are dealing with the abdomen for purposes of diagnosis, you can never be too delicate with your manipulations. If you handle the patient too roughly, you will frighten her, she will contract her muscles, and you will not learn a great many things which it is advisable that you should learn. If you handle patients roughly in operations, there is also danger that you may do them some harm.

I have now learned, by passing my hands gently over the abdomen in this case, several things. In the first place, the case is not one of pregnancy, although of this I had satisfied myself before; secondly, it is not a parovarian tumor; and I have also learned that, in the third place, it is probably a small growth with a large ascitic effusion. Just at this place in the lower portion of the abdomen there is a small solid mass, and there is a larger one in the upper part which is not solid.

Now, my task shall be to find out what relation there is, if any, between the two masses. Here, in the epigastric region, I get a tympanitic, an intestinal, note upon percussion, and also a wave of fluctuation; low down it is dull. This was very useful to the man who tapped her, and upon it he probably based his diagnosis, and it would have given us considerably more information if the case had not been tapped; but now I am unable to say which of two conditions that may be present is before us, although it is important to know this, for upon it depends the advice we will give in the case. This softer portion may be an ovarian cyst which has partially collapsed after being emptied by tapping, or it may be an abdominal effusion. If it is the former, and an ordinary multicystic tumor, the treatment is perfectly easy and the result will be favorable; if, on the contrary, it is a small tumor surrounded by a large quantity of ascitic fluid, the state of the case is very much altered, and there are several things to be considered. I have found in the pelvis a small tumor over to the left, which may be the ovary in a state of incipient cystoma; it may be a papilloma, or it may be a malignant proliferation from some of the viscera. It is important to find out which of these it is. Now that we have fluid in the abdomen, it is impossible to come to a very definite conclusion, but could we have seen the patient before she was tapped, the relations of the intestines and the fluid would have aided the diagnosis. The growth may have been from a cyst of the ovary, but I think myself that the fluid was not removed from a cyst,—that it was ascitic; and it is probable that this tumor here is a papilloma. So far as I read the history, I think that the second is rather more likely.

Under these circumstances, what are you to do for such a patient? The first thing to do is to open the abdomen in either case. My experience teaches me that it is a surgical crime to allow a patient to go to her grave without an operation, where it offers a possibility of relief.

This leads me to speak of the condition of papilloma, which is generally regarded as most unfavorable. Now, on account of reasons which to you are evident, it is possible to speak more freely in the patient's absence than in her presence; and she will, therefore, be removed. I said that I would return to the subject of tapping. It is not at all an innocent operation, though it is not considered a misdeed to tap by many physicians. In my own country the practice of tapping still prevails, and, possibly, in this country: so I have not too much to say when a case is brought to me for operation after it has been tapped; but in my opinion there are very few cases in which it is justifiable to tap a patient; the only exception I would make would be in malignant disease. Let me say with regard to the effects of tapping upon the subsequent mortality after operation, that I have not lost a case after ovariotomy for several years, except those which had been previously tapped. It is perfectly positive that the greatest danger in a case does not come from adhesions, or such complications, but from tapping. No matter how difficult the case was, if it had not been tapped it did well. I think that the explanation is a chemical one. The fluids in the interior of cysts are very rich in some complex

kinds of albumen. I have made very many examinations of these fluids, testing them after various methods, and have come to the conclusion that no two kinds of cysts have fluids exactly alike. But all the cases I have lost were cases which had been previously tapped. I think that the reason for this lies in the physiological fact that the removal of this albuminous fluid renders the blood more coagulable. After the operation, the clot which forms in the pedicle runs backward in the vessels, and causes death from cardiac thrombosis.

My experience, therefore, makes me say that there should be no tapping. When a patient with an abdominal growth, ovarian or not, comes into the hands of a physician, his duty is either to remove the tumor without delay, if his experience and aptitude for operating are sufficient to undertake the case himself, or, if not, to hand it over to the care of one of his colleagues who has the skill and ability, for the credit of abdominal surgery, which both of them represent and desire to honor.

To return to our case: this patient has been tapped, and my impression is that the fluid was ascitic. The position of the punctures is above the line of the ordinary place for tapping ovarian cysts; the surgeon who did this tapping probably felt this comparatively solid tumor at the base, and believed himself more likely to reach fluid at this point than lower down, at the point of election. This, of course, is based upon the supposition that you are accustomed to follow the same rule that surgeons at home are, of tapping usually about half-way between the umbilicus and the pubes.

With regard to tapping, I rarely find myself called upon to perform tapping in preference to ovariotomy. I do not find the objection on the part of patients to operating that existed ten or twenty years ago, but I have not had a patient for the last five or six years who urged such objection or refused operation. When you can say positively, as you now may, that ninety-six per cent. of such operations should get well, you are not likely to meet with refusal. But, you may say, are there not cases which have been tapped many times without apparent injury?

I remember that I saw in the county of Hants a tombstone that bore an inscription declaring that the deceased had been tapped for ovarian dropsy forty-seven times. Being on a tombstone, of course it must be true: if so, this is the largest number of such tappings on record. My reply is that these large cysts are generally not ovarian but parovarian cysts; they are filled with a fluid of low density, which contains almost no albumen, and very little salts. Now, it is easy to conceive that in a single large cyst with a fluid which does not contain much albumen, the tumor may be tapped many times without weakening the patient very much; but in an ovarian cyst filled with albuminous fluid the result would be very different. This fact, then, would be no argument in favor of a change in treatment and a return to the practice of tapping ovarian cysts, a practice which is now less frequent in England than it used to be, chiefly through the efforts of my friend Dr. Bantock and myself.

An early operation is advisable. The patient is not subjected to the physical labor of carrying around a large growth, she is less likely to have papilloma, and, finally, if a young woman, she will be glad to be relieved of the annoyance, if not more, of exciting observation by her large abdomen. The surgeon will find an early operation desirable, because the tumor is small and more easily removed, he will be less likely to find adhesions, the operation will be more readily done, there are fewer chances of having recurrent attacks of inflammation or peritonitis afterwards, and, finally, the danger from early operations is almost *nil.* I have little hesitation in saying that, in a series of early operations, where there had been no tapping, the mortality would not be over one per cent. If you should hear the contrary opinion expressed with regard to tapping from that I have just given you, you will find generally that it is by a white-haired man, while you will hear the opinion that I have expressed from those whose hair is brown or just on the turn; that is, the younger men advocate this view, the older men condemn it. I do not mean to imply that young men are always right and that old men must be wrong. There is a proverb, "Young men think old men fools, but old men know that young men are fools." I mean simply to teach that science is constantly progressing from age to age, and that each age is something in advance of that which preceded it.

Perhaps I ought to say one word about this case in conclusion. Suppose that I be-

lieved that this patient was suffering from papilloma—the disease which we so much dread after opening the abdomen—developing around a tumor: I would still proceed to remove the tumor, even if I were certain that papilloma were present. And my reason for this is a very curious one. I cannot pretend to explain it, but the occurrence is one of which I am quite certain. I cannot say without my figures before me just how many times I have met with this condition, but it is certainly a hundred times. In operations especially, and in large proportion in ovarian tumors, also in cysts of the parovarium and in myoma, and sometimes when there was no tumor at all, when I opened the abdomen for exploratory purposes, without knowing what I would find, have I encountered this curious velvety condition of the peritoneum which I recognized as papilloma. I remember a case seen by Mr. Pemberton, my colleague at Birmingham. The patient, a young lady, had an enormously enlarged abdomen, due to ascites, a fact I had recognized. I opened it by incision, as my practice is to make a small incision for exploration and drainage; by this means the fluid is evacuated just as well as with the trocar; but you cannot feel anything with a trocar, but with a clean cut of two or three inches you can introduce one or two fingers, and find out the actual condition of the pelvic organs as you can in no other way. I may add that I always make the exploratory incision for the removal of fluid, and find that it readily heals. Now, in this case of which I am speaking, I opened the abdomen and I found the peritoneum universally covered with papilloma. I simply put in a drainage-tube and cured the patient. It is now four years since this was done, and the patient remains entirely well.

I recall another case which I operated upon several years ago. Papilloma was present, and I was obliged to leave two masses in the abdomen. She is now about sixty-five years of age, the tumors have entirely disappeared, and she is perfectly well.

I have, therefore, concluded that there are two kinds of papilloma, malignant and non-malignant: one kills the patient in a few weeks or months, and from the other the patient will recover after an operation. I have carefully taken specimens from each and subjected them to microscopical examination, and competent experts could find no difference whatever. The non-malignant cannot be distinguished from the other. There is no question but that there are certain cases, however, in which it is malignant, nor that in others it is perfectly curable. So that, even if I knew this to be a case of papilloma, I would open the abdomen, and, if possible, remove it, for it is possible that by the removal of the tumor I may cure the patient.

I said, "if possible," to remove the tumor. This reminds me that, after opening the abdomen, you must (let me use an American word here) "prospect" a little, and make up your mind fully what you shall do. The most fatal operations are those which have been abandoned after removal of a portion of the growth. If you remove part of the tumor and feel tired, and feel like closing the abdomen, remember that you are exposing your patient to a condition the mortality of which is about sixty per cent., but, if you have the courage to finish the operation, you may cure your patient.

In these cases, of course, skill in manipulation is necessary, and this will come by experience. If your experience and courage are not equal to the operation, place your patient in other hands, and the result will be a better one for your reputation and for the patient.

REMARKS UPON EXPLORATORY LAPAROTOMY AND REMOVAL OF THE UTERINE APPENDAGES.

The next case is one which involves considerable difficulty in diagnosis, and requires a knowledge of the past history of the patient in order properly to decide the question of treatment. This knowledge I have only very imperfectly obtained from my few moments' conversation with her, but I will take it for granted that the young girl's sufferings are real and intense as she states, and that everything has been done for her relief that could be done by medical means. Now, I might supplement this by giving you an account of a similar case which I operated upon the other day in the State of New York, where the history was better known to me than this one is, or I might cite some cases under my own care at home, which were treated by removal of the diseased uterine appendages; but I will not take up your time with such accounts, because I wish to discuss with you a few points in relation to the operation itself as compared with other means of treatment.

She is a young girl, 21 years of age, and has a pronounced crop of acne upon her face. When a woman comes into my consultation-room with a crop of acne, I always ask for a copy of the prescription that she has been taking, and I expect to find that it is bromide of potassium, which is the fashionable drug in the practice of some physicians for all the ills that women suffer from. I never met with anybody who could swear that he cured any woman with it, but it is a convenient pump-handle and appears to be diligently worked.

I usually am told, in answer to my questions as to previous treatment in these cases, "Oh, yes; I have taken lots of bromides. I went to Dr. A., Dr. B., Dr. C., Dr. D., Dr. E., and Dr. F., and Dr. A. gave me bromide of potassium, Dr. B. gave me bromide of sodium, Dr. C. gave me bromide of ammonium," and so on. The latest that I heard of was the bromide of nickel. Finally, she stumbles upon Dr. F., who puts in a pessary; for what, goodness knows, but he finds her ailing, and puts in a pessary, and the chances are that it does harm instead of good.

I removed a pair of Fallopian tubes crammed full of pus, just before I left England, from a woman who had spent eighteen months not in "riotous living," but in going round through a course of doctors. Another patient had a tray-full of pessaries, of various shapes and sizes. She would exhibit them as curiosities. "This one," she would say, taking one up in her fingers, "was inserted by Dr. A., and I wore it a week; Dr. B. introduced this one, and I could only wear it a few days; and this one must have been invented by the devil himself, for I could not wear it at all."

To return to our supposed case: she finally leaves the pessary-doctors, and the bromides, and goes to another, who dilates and splits the cervix uteri. So she goes from one quack to another, until she comes under the care of a surgeon who will operate and relieve her. I do not mean to declare that all women suffering with menstrual disorders require operation; by no means; although I have been misrepresented as saying this. I have never said it. But I mean to say that a large number of cases of these suffering women demand and require relief by operation; and of this class I believe that our patient here is one.

Now, if a woman with a history of wandering about for a considerable period among different physicians, seeking relief from menstrual disorders and finding none, who has used various contrivances without benefit, and taken many drugs, almost to the destruction of her health, comes to you, and you are persuaded from the account she gives of herself that her sufferings are real and not imaginary, you are justified in making a small incision in the abdomen and in putting your fingers down into the pelvis to find out if you can relieve her.

I have been accused of abusing this operation, but, I think, unjustly. Every new operation is liable to be abused, but increasing experience soon teaches its proper limits.

I said that before operating you should be satisfied that the patient's sufferings are real and not imaginary. How can we ascertain if the patient's sufferings are real? Now, in my experience, I have always found that if, after putting the operation conscientiously and fully before the patient, she consents to undergo it I have never operated without finding something the matter that would warrant the operation. You may say that this is placing too much responsibility upon the patient; but is it not what we have to do in other departments of surgery? A man comes with a chronic disease of the knee requiring operation,—amputation or excision. The surgeon explains the risks and advantages of each operation to the patient, and recommends one or the other, but the patient must take the responsibility of deciding. I always explain the operation carefully, and say that I will consult with her medical attendant or any number of them that she wishes, but the result of the consultation must be laid before the patient, and she must take a large share of the responsibility in the decision.

There are persons who have declared that this operation is done for low and immoral purposes. The first reply to this is that the operation is always done in such a public way as to refute any such charge. It cannot be done without being known: there are always nurses in attendance, who would tell of it, and it could not be kept secret. It is true, I have been approached by women who did not wish to bear any children; but we have some conscience left; and those who perform this operation are not to be considered as having less scruples than other surgeons. Moreover,

as I have just said, the operation is a semi-public one, and it would soon be known if it were done with such motives. So far as I know, it has never been openly and directly charged upon any one in England that an operation of this kind was done for immoral purposes.

It has also been said that the operation is done sometimes for another immoral purpose,—simply on account of the fee. But if this is brought to me, it might raise the same question with regard to the others who give bromides, put in pessaries, or divide the cervix. I think that the balance of the argument is in my favor: at all events, I have thrown down the gauntlet in England, and no one has yet taken it up.

Now, to return to this young girl. She is obliged to work for her living. Circumstances are very much against a patient who must earn her own living, as compared with one in comfortable circumstances in her own home. Luxury is much in favor of relief from ovarian disorders. A woman who can rest during her painful menstrual period is better situated for recovery than one who is obliged to work for one week in every month while suffering, and the latter requires relief by operation more decidedly than the former.

When a woman like this comes before you, who is compelled to work in order to live, and for one week in the month is incapacitated from working, you may be certain that stopping menstruation will give her relief, and you can do so just as truly as, in another patient whose eyes only see at twenty feet, you may by proper glasses enable him to see at a normal distance.

In this case, I have no doubt, if I could examine her, I would find her Fallopian tubes in a state of inflammation; but, even if they were found to be perfectly healthy, it would be better to remove them and stop this terrible suffering at each menstrual period.

About the consequences of the operation let me speak a word. I recall that a certain eminent ecclesiastic opposed the practice of vaccination and publicly stated in a sermon that dreadful things, such as a cloven hoof, and horns upon the head, would be caused by it. Now, it appears that we are treated in much the same way about this operation. We are told that the patients will get masculine, and that there will be an overgrowth of fatty tissue, and various other imaginary results. I am reminded, when I hear this, of the German professor who evolved a camel from his inner consciousness. It is well known, from the practice in Eastern countries of removing the testicles in men and ovaries from women, that, if the operation be done before puberty, the patient will retain to some extent the infantile type: the hair does not develop upon the face, nor does the voice change in men; but these consequences do not occur when the operation is performed after adult age has been reached. I have removed the ovaries in many cases and for various diseases, and I have never seen any of these asserted bad results, and no changes in the condition of the individual except for the better.

These ridiculous exaggerations I have referred to you will find in the first edition of Spencer Wells, and to my surprise I found them still more marked in the second edition: they are without any foundation in fact whatever. On the contrary, in the great majority of cases there is immediate relief from the sufferings and from loss of blood. Perhaps entire relief may be delayed for several months, and in some cases it may not come at all; but, I ask you, is this a valid argument against the operation? The operation for cataract sometimes fails, there is suppuration of the globe, irido-cyclitis, or other accidents which may lead to failure; and I might bring examples from other departments of surgery that would also illustrate this point. In fact, the operation of ovariotomy for the relief of pain and hemorrhage gives good results in comparison with other operations.

It is true that woman may have some inconveniences associated with the climacteric, but she would be obliged to go through them some time or other if she lived: they are part of her menstrual life. Some women have very little trouble, while others have a good deal and may become drunkards, etc. Fortunately, I have never seen any such results following the operation.

There is one condition, however, which I have seen develop after ovariotomy, after removal of one or both ovaries, and even also removal of the uterus. It is a condition of acute melancholia. I have operated now over nine hundred times, and have seen seven such cases in all. Taking

into account the fact that I lost more of my earlier operations, I think that we may take it for granted that about one per cent. of our cases will take on this form of insanity and will die with the disease. I do not know if other surgeons have met with anything like so many cases in their operations; but we must bear in mind that for some unaccountable reason certain of our cases will be attacked by melancholia. It is the one objectionable point in the operation of which I am aware.

UTERINE MYOMA.

The next case is one of myoma of the uterus; in fact, we have two cases, which I will briefly discuss, without bringing them in, since you could feel nothing, and certainly can see nothing, of the disease.

The first case is 48 years of age, and does not have very much hemorrhage, and I do not believe that she suffers very much pain. In her the tumor is very hard and consolidated. I think that this belongs to the class of cases in which nature is curing the disease and thus gradually relieving the symptoms. The other woman is 40 years of age, and has had hemorrhages: being younger than the former woman, an operation may be taken into consideration, since she has to be tided over some years before her climacteric.

We did not use to operate upon women with myoma, and now, if the patient is forty-seven, we do not operate before giving ergot a faithful trial; but in younger women, under forty, it becomes a very important question. It is a question in which the patient must take a good deal of the responsibility in answering, and contribute a good deal to the answer.

If the patient suffers every month, and loses blood for a week or more, this question comes up: is it preferable for the patient, say thirty-six years old, to go on for twelve or fourteen years suffering in this way, or to perform an operation the mortality of which is about four per cent.? I can only say that if I were the patient I should have the operation done.

Now, this is comparatively a common affection, and we meet with it often, especially in the colored race, in the dissecting-room and post-mortem table, in cases where it gave absolutely no trouble during life, so that we have come to look upon it as of little importance. We are laboring under some traditions with regard to uterine myoma, and this is one of them,—that it is an insignificant affection. I need hardly stop to say that those myomas that give no trouble during life are not the ones that trouble us: it is those that *do* give trouble that apply to us for relief, which it is our duty to give them.

Another tradition with regard to myoma is that it will cease at the climacteric and give no further trouble; but we find that in many of these cases the growths go on developing for years after the menopause should occur, and the patient suffers from hemorrhages that severely affect her health.

There are two operations for the relief of uterine myoma: you may remove the uterine appendages, and by this you remove the tendency to these troubles which afflict the poor patient. It has been now several years—six or seven, perhaps—during which I have employed the operation, which I consider the proper one, as the hemorrhage almost always ceases soon after its performance. The other operation is the removal of the uterus itself; and this may be done if the hemorrhage does not cease after the removal of the uterine appendages.

Now I have come to the end of my cases, and have exceeded my time. What I have brought before you has not possessed the usual interest of a surgical clinic; but I hope that you will pardon that, in view of the important subjects which I have presented for your consideration. Any faults in the lecture you must attribute to my want of experience in lecturing. I have never delivered a clinical lecture in my life until a week ago. It seems to be very unfortunate that in England it is difficult for those who have experience to get the opportunity of teaching, while those who do the teaching have not the clinical experience. You must take what I have said, therefore, not as a lesson from a British teacher, but purely as the views of a British surgeon.

IMPOTENCE IN THE MALE.—Dr. Hammond, of New York, has employed the following with satisfactory results:

℞ Strychninæ sulphatis, gr. j;
Acid. phosphorici dilut., f℥j.

Ten drops to be taken in a teaspoonful of the fluid extract of coca three times daily, before meals.

ORIGINAL COMMUNICATIONS.

SOME OF THE USES OF THE VAGINAL TAMPON IN DISEASES OF WOMEN, AND IN OBSTETRICS.

An Address delivered before the Lehigh District Medical Society at Mauch Chunk, August 19, 1884,

BY THEOPHILUS PARVIN, M.D.,

Professor of Obstetrics and Diseases of Women and Children in the Jefferson Medical College, Philadelphia.

IT was said that all roads led to Rome: in like manner, I have been informed that all addresses before your body are upon strictly professional subjects, thus leading to the one great end of medicine, the cure of the sick. In compliance with your design, and obedient to honored usage, my effort shall be to present a practical subject, the consideration of which it is hoped may be of some interest and usefulness. In announcing that subject as *Some of the Uses of the Tampon in Gynæcology and in Obstetrics*, let me make peace with those who possibly now think the theme and its discussion too elementary for the occasion,—being wise enough to know that one does not look for whales in the Euxine. For a moment conceding the force of the criticism, still an experience of more than thirty years of active professional work has taught me that my own failures and shortcomings, sins—I had almost said crimes—of omission and commission, were much more frequent in little than in great matters. In truth, observation likewise tells me that minor medicine and minor surgery often become major medicine and major surgery in their results for good or for evil. As it is urged in the religious life to learn from time to time that the foundation of one's faith is broad and strong, in order that the superstructure shall be durable, so in our medical life it may not be amiss, upon occasion, to consider even elementary questions, in order that, our knowledge being clearer and more certain, our judgment and action in emergencies will be unclouded with doubts, undelayed by hesitancy. Peradventure such study may have more practical value for all than a description of the most recently discovered microbe, or a discussion concerning the value of this week's favorite antiseptic.

Further, find me a single text-book upon diseases of women or one upon obstetrics in which the varied uses of the tampon are fully set forth, and I will confess my mistake in the selection of a subject. Let me add, however, that Dr. Mundé has presented with commendable fulness of information and richness of detail the chief applications of the tampon in diseases of women in his well-known and valuable work; but that is not a complete treatise upon diseases of females,—only a book of so-called minor surgical gynæcology,—so that the challenge cannot be met by it.

Finally, it may happen, even in the partial study of the subject which the usual time of an address permits, that questions which are very far from being so simple and elementary as might be imagined may be presented.

Having said this much in explanation, hardly in apology, I pass to the consideration of the subject.

The tampon is one of the most ancient of therapeutic means. Many of the great masters in the past have recognized its value. Among the different pessaries recommended by Hippocrates* is one for menorrhagia, made of wool impregnated with different substances, and then introduced into the vagina,—plainly a tampon. Paul of Ægina† said that an admirable remedy for uterine hemorrhage was a sponge cooked in wine or in liquid pitch and applied. Moschion, who belonged to the age of Nero, recommended the tampon in uterine hemorrhage. By a writer also of one of the early Christian centuries a detailed description of a tampon for this purpose is given.‡ This tampon was made of powdered pennyroyal, galanga, spikenard, nutmeg, and cloves, mixed with an oil, and then placed in a linen cloth *veterem, rarem, et subtilem*, tying securely the powders in the linen, and the mass, having been formed in *modum pilæ*, was passed into the vagina, and secured by means of a bandage externally. No one can doubt the mechanical effect of a tampon thus made and applied. For the same disorder Ambrose Paré advised quinces roasted under the coals and incorporated with powder of

* Eighth volume of Littré's Hippocrates, p. 381.

† Sydenham Society's Edition.

‡ The following is the prescription found in *Gynæciorum*, etc.: Pulverem pulegii; galangas, spice nardi, nucis muscatæ, caryophyllatæ; misce, distempera cum oleo muscellino, vel pulegino. Et accipe pannum lineum veterem, rarem, et subtilem, et intus liga hos pulveres, formandum ad modum pilæ. Et matrice intromissa, os vulvæ cum dicta ut matrix iterum non exeat: et pilam ibi cum fascia superliga, ut non possit exire: et fascia transfire retro usq. ad renes et intra ilia, et ibi ligetur.

myrtle and Armenian bole, then passed into the vagina.

The primary idea involved in the word tampon is that of a plug introduced into a cavity for the arrest of hemorrhage, and thus the tampon was used by many in ancient times; but, as we have seen, the old masters sought also to make it the vehicle for medicinal substances. Modern practice recognizes not only each of these uses, but others also. It will be convenient in the discussion of the subject to refer, first, to the uses of the tampon in diseases of women, and then in obstetric practice. Chrobak* describes the former under three heads: "First, the tampon is used to retain the dressing used after bilateral division of the cervix; a tent, or a stem pessary, to lessen the mobility of the uterus or to keep it in position after it has been replaced.

"Second, it is used for compression, and for the protection of ulcerated, eroded, or wounded parts from friction; it also absorbs their secretion and prevents that of the vagina from coming in contact with them.

"Third, it is used in hemorrhage, and in congenital or acquired contraction of the vagina."

The application of the tampon for the arrest of hemorrhage will be considered in connection with its obstetric uses; and as to the others in the list, time will permit only a few to be presented.

First, the tampon in certain uterine disorders of position. Doubtless the first of these in which the tampon was used was prolapse. Here, usually, the tampon presents an obstacle which, by its greater size, prevents the descent of the uterus. Sponges, rubber bags introduced into the vagina empty and then filled with air, a mass of cotton, of tow, and of other substances, have been thus used.

Dr. Copeman† reported, in 1874, a very interesting case of aggravated prolapse of the uterus successfully treated by a tow pessary; the tow "was covered at the top by, and partially enclosed in, a piece of linen greased on the outside to facilitate its introduction." I think it ought to be added that the external greasing of such a pessary ought to be done not merely to facilitate its introduction, but to prevent its irritating the part of the neck of the uterus resting upon it, and the vaginal walls with which it is in contact: a tow pessary or tampon, even when partially covered with linen, if worn for any length of time, or frequently reintroduced, must cause considerable irritation.

But in those cases where the vagina retains its normal curvature, it is not necessary to have so large a tampon in order to secure support for the uterus. Archimedes, enthusiastic over the discovery of the great power of the lever, would move the world if he could find a place whereon to stand; and so the uterus can be upheld by a tampon which has its base resting upon the posterior wall of the vagina. This point will be made plainer in speaking of retroversion of the uterus, a positional disorder which always precedes prolapse.

As is now well established, posterior displacements of the uterus are more frequent in those who have had miscarriages or borne one or more children, and therefore oftener are brought to the notice of the physician. Moreover,‡ anteversion of the uterus, the bladder being empty, is normal in the parous, and therefore requires no treatment; while in the nulliparous, the uterus in a similar condition of the bladder is slightly anteflexed as well as anteverted, and then also no treatment is needed. Without considering the etiology and the diagnosis of posterior displacements,—the one not always clear, and the other usually very plain,—let me refer exclusively to the treatment of retroversion. Such positional disorder is only possible when the utero-sacral and round ligaments are greatly stretched, and such disorder is only permanently cured when these ligaments have been shortened, or, in other words, have resumed their normal length. The artificial shortening of the round ligaments, as proposed by Alexander, and successfully practised by him and others, for uterine prolapse, is conclusive proof, if any were necessary, of the elongation of those ligaments which occurs in a posterior displacement of the uterus. In the cure of the disorder it is important to give these uterine upholding bands rest, or at least restrict their action so far as can be done without seriously interfering with the normal mobility of the uterus. The practical bearing of this statement will be seen in the consideration of the special means of treatment recommended.

* See Billroth's Handbuch der Frauenkrankheiten.
† British Medical Journal, October, 1874.

‡ See Schultze's recent work, translated by Hergott, Traité sur les Déviations utérines.

Provided there be no restraining adhesions, the restoration of the uterus to its normal position is not difficult either with the fingers or the sound. Since the publication of Dr. Henry F. Campbell's* paper upon pneumatic self-replacement of the uterus, it has been held that the retroverted womb can be put in position by having the patient take the knee-chest position and permitting air to be admitted into the vagina. But the investigations† of Simpson and Hart show that in this position the retroverted uterus, while farther from the pelvic outlet, is more retroverted. How fallacious does our professional experience often prove! Doubtless hundreds of patients have, by direction of their physicians, daily or semi-daily taken this position, and, as both doctors and patients believed, the results were beneficial. Probably the only benefit was the temporary partial anæmia of congested organs and tissues. Nevertheless, although this position does not possess the advantages which have been attributed to it, and although justly characterized by Hart as "awkward and inconvenient," yet it is possible in it to correct a retroversion by the use of the finger in the vagina, or by means of the tenaculum, and then by a properly-applied tampon to keep the uterus in place. Nay, more, the elongation of the vagina which then occurs permits the tampon to be placed higher, fixing the uterus in a more elevated position than can be done when the patient is lying upon her side. However, the advantages in most cases do not compensate for the inconveniences and disagreeableness of the attitude, so that it may be dispensed with in most cases.

Whether the uterus be restored by finger, sound, tenaculum, or position, or by two or more of these combined, restoration must be followed by retention: the errant organ has been put in place, it must be kept in place. If the malposition be all, if the organ itself be healthy and there be no disease of structures adjacent to it, we have no better instrument for general use than the horseshoe pessary of the late Dr. Hodge, especially as modified by Dr. Albert H. Smith. But in how many patients do we find the body, and especially the neck, of the uterus diseased, or the consequences of intra-pelvic inflammation, or an enlarged, tender, sensitive, partially-prolapsed ovary! Very many patients cannot at first bear a rigid support for the womb, the parts upon which a solid pessary presses are too sensitive, and the condition of a patient may be rendered much worse by such instrument. Among the pathological conditions which the cervix may present are unhealed tears that occurred in childbirth. These tears may be quite sensitive, secreting a more or less abundant, opaque matter, and red, bleeding upon the touch with finger or sound. And here let me refer for a moment to the subject which has engaged so much professional attention in this country during the last few years, tears of the neck of the womb, or, as more commonly, though not any more correctly, called, lacerations of the cervix. The latter expression may sound more scientific, and, possibly, in the mind of the sufferer magnifies the disease. The brilliant discovery made by Dr. Emmet a few years ago, and the very satisfactory results which follow the operation known by his name, when that operation is done in suitable cases, all know. But that the frequency and the importance of the accident have been greatly exaggerated, and that an operation for the cure of tears has been many a time unnecessarily performed, I do not doubt. Nay, further, more than once a woman has been made most unhappy by being told that her womb had been so badly torn in her labor that she would never be well until an operation was made, yet in such cases an examination made by competent men, who were too intelligent to be hobby-riders, found no lesions of the cervix, nothing but the ordinary boundary between anterior and posterior lips which the first labor makes. Many a practitioner has suffered unjust reproach because of such alleged injuries in childbirth.

Standing now in my fourth decade of professional life, I have seen changes in the theory and in the therapeutics of diseases of women as remarkable as those which Julian Hawthorne has described as occurring in Archibald Malmaison. I remember, as if it were but yesterday, how one of my own most honored teachers insisted upon irritable uterus as the most important fact in uterine pathology, and that this irritability was the result of displacement of the organ, a displacement which was to be

* Transactions of the American Gynæcological Society, vol. i.

† Female Pelvic Anatomy, by D. Berry Hart, M.D.

remedied by a properly-adjusted pessary. Then the inflammation theory had its day of general acceptance. For a time, leucorrhœa, a mere symptom of several conditions, was not only made a disease, but claimed to open all uterine pathology.

Some years ago, the profession, under the guidance of the illustrious Sir James Simpson, became enthusiastic in praise of bilateral division of the neck of the womb for the cure of dysmenorrhœa and of sterility, but to-day the operation is not done in one of fifty cases in which it would have been done twenty years ago. I also believe that the operation for tears in the neck of the womb will not be done twenty years hence with anything like the frequency with which many now do it. Some of us are slow to think that nature is so cruel to woman in the exercise of her highest bodily function, giving birth to a child, that she necessarily suffers such tearing of her uterus in one case in three—or one in twenty—that it must be repaired by a surgical operation. On the other hand, some of us are slow to think that obstetric practitioners are so ignorant or so cruel that they permit or cause such accidents. It is exceptional when a woman first gives birth to a child that the os uteri is not torn; the chief tears are at the sides, especially the left side of the os; such tears at the side make the distinction between the anterior and the posterior lip, for before childbirth the mouth of the uterus presents a uniform rim or boundary. As a rule, these rents extend only through the crown of the neck, but occasionally beyond it, in rare cases to the vaginal junction. De Sinéty,* in the last edition of his excellent work, remarks that the indications for Emmet's operation are rarely presented; and at the other extreme are those who find them so frequently presented. The latter seem to have the notion that nature does wrong in suffering the mouth of the womb to be torn, and hold, practically at least, that it is the duty of the physician to restore by a plastic operation every parous to a nulliparous uterus, for, as before said, the rule is that there is some tearing of the mouth of the womb in childbirth. In fact, one might possibly express the practice and teaching of these enthusiastic devotees of the operation by parodying the advice given as to the use of a shillalah at Donnybrook Fair,—"Whenever you see a head, hit it:" whenever you see a tear, stitch it. But a tear that neither by eversion of its margins, ectropion, by local or reflex pain, by spontaneous pain, or that evoked by touch, by leucorrhœa, or by menstrual disorder, makes complaint, does not need a plastic operation: the part is too hidden from public view to demand an operation purely upon æsthetic grounds. There are opinions which claim for the operation a prophylactic power against cancer of the organ; but the large and accurate statistics are wanting to prove the correctness of the opinions.

Some who oppose human cremation claim that the ends of justice may be defeated by this process of disposing of dead bodies, their identification being impossible, and thus criminals may escape. Possibly as specious an argument will be suggested against Emmet's operation; for are there not some operators so skilful that they can convert the parous into the nulliparous os, and thus even an expert be deceived, declaring that a woman had never given birth to a child when she may have had several? But, speaking seriously, when such perfect restoration of the external os uteri is accomplished, tearing in a subsequent labor that may occur is almost inevitable.

But, again, many of these tears which make complaint by local disturbance, leucorrhœa, menorrhagia, and pain,—tears which present admirable opportunities and invitations for plastic operations,—can be healed by proper local treatment without scissors and stitches. And this brings me to the application of the vaginal tampon for the cure of uterine retroversion, and certain diseases of the neck of the womb, especially its minor lacerations or tears. The tampon is used in these cases not merely as a support to the uterus, but for compression, and as a means of continuous application of medicinal substances to a diseased part. The medicinal agent which is of most value used with the tampon is iodoform; and a word or two as to this medicine and its application in diseases of women. Iodoform was discovered in 1824, and first used as a medicine in 1836; its antiseptic properties were made known in 1853, and in 1866 it was applied locally and used internally in the treatment of uterine cancer by Eastlake.† It has not

* Traité pratique de Gynécologie, Paris, 1884.

† Transactions of the London Obstetrical Society, vol. vii.

only a decided antiseptic but also an analgesic property; besides, it is absorbed when applied to the neck of the uterus or to the walls of the vagina, appearing in the urine in the form of sodium iodide, and therefore the power of producing absorption belonging to iodine or its alkaline compounds may be claimed for it.

An objection to the free local use of iodoform was at first its expense; but this is no longer of any force, for the medicine can be had at wholesale for four dollars a pound. Another objection to it was its very unpleasant odor; and this objection has never been altogether done away with. Various deodorizing substances have been recommended, such as some of the essential oils, and balsam of Peru; and Rosetig* finally gave his preference to tonka bean, a bean doubtless more familiar to tobacconists than to doctors, and among German snuff-takers a not uncommon content of a snuff-box.

From the specimens which I show you of iodoform ointment I think you will conclude that oil of bitter almonds is the best deodorizer; balsam of Peru is objectionable because it produces partial decomposition of the iodoform with liberation of iodine, and the same holds true of oil of gaultheria. As may be seen by this specimen of iodoform cotton, partial decomposition of the iodoform occurs from the addition of gaultheria, and this change may be attributed to a reaction between the salicylate of methyl and the iodoform.

The form in which iodoform is most frequently used in diseases of women is that of ointment. Martin, for example, who has given† iodoform the highest praise, saying, after a series of applications of it in different uterine diseases, that its value could not be overestimated, used it as an ointment made by combining it with vaseline and lard, adding a few drops of peppermint oil or of balsam of Peru: he used this not only as a vaginal suppository, but also had it rubbed into the hypogastrium. Odebrecht used it as a rectal suppository, and commended its value especially in chronic exudative processes. The only form in which I have used it is that of an ointment composed of one to three drachms of iodoform to an ounce of vaseline. Another form in which I doubt not it may be usefully employed is that of iodoform cotton, some specimens of which as recently made for me by Mr. Harris, in the drug-store of Blair's Sons, Philadelphia, are now shown you. It is made by dipping absorbent cotton in a saturated ethereal solution of iodoform; after the ether has evaporated the cotton has doubled its weight from the added iodoform; that is to say, one hundred grains of iodoform cotton contains fifty grains of iodoform. I think the value of this preparation will prove to be great; it may be used, for example, in place of the ordinary iodoform suppositories in the vagina, both as an analgesic and where a strong disinfectant effect is sought; it would be useful as the part of the tampon applied to the os uteri in a case of abortion where tamponing the vagina is necessary. Certainly, too, the absorption of the agent would be greater if thus used than when incorporated with a fatty body or when mixed with glycerin.

Tamponing the vagina, as well as the application of iodoform, I was led to adopt upon the recommendation of Dr. Taliaferro, a distinguished practitioner and teacher of Atlanta, Georgia, he having published his method and its success a few years ago.

Probably the best material for a vaginal tampon in general is absorbent cotton. Marine lint has been proposed; but this is so harsh I doubt if the tampon made of it could be properly introduced without pain, or worn without causing more or less vaginal irritation.

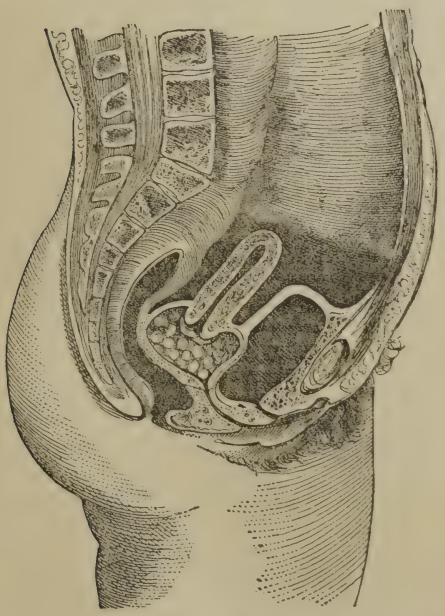
Preparing for the application of the tampon in these cases, one needs ten or twelve round masses of the absorbent cotton, each being somewhat less than a hulled walnut; next, have a piece of cotton, either with or without being first dipped in glycerin, formed into something of a cup-shape, and in the concavity put at least a drachm of iodoform ointment. The instruments needed are a pair of long, curved forceps, and a Sims's or a Simon's speculum. Let me here remark, by the way, that the Sims instrument, as often found in the shops, has altogether too narrow and concave a blade: a broad, shallow blade will prove more useful.

The patient lies on either the gynæcological table or on a hard bed, usually upon her left side, the under arm thrown behind, the lower limbs flexed, and the upper one thrown forward so that the knee touches

* Wien. Med. Wochenschrift, 1881, No. 43.
† Berlin. Klin. Wochenschrift, March 14, 1881.

the couch or table. After introducing the speculum and drawing back the perineum, the position of the uterus is examined, and, if the organ be still retroverted, it is put in normal position by the finger or by a tenaculum hooked in either lip, or simply by passing one or more of the cotton tampons high up in the posterior vaginal cul-de-sac, so as to press the body of the uterus forward, or by tampons placed anteriorly so as to push the neck backward: this done, the entire vaginal vault is filled with the cotton balls, and then the iodoform tampon placed directly over the os uteri; two or three more tampons are then introduced, endeavoring to build a column the base of which shall rest chiefly upon the posterior vaginal wall, and its anterior side upon the anterior wall. The S-shaped curvature of the vagina should, as Chrobak has stated,* be preserved, for

Fig. 1.



there support must come, as well as from the normal apposition of the two walls, and hence the tampon ought to occupy no more than the upper third, or at most upper half, of the vagina (Fig. 1). It is rarely that patients do not from the first find relief from the cotton packing, if properly done, in pronounced uterine retroversion, while congestion, and raw, unhealed, pus-

* Op. cit.

secreting, and readily-bleeding tears of the neck, are gradually relieved and often finally cured. I have seen several cases of cervical tears in which Emmet's operation had been advised—some, indeed, in which I thought it probably would be necessary—entirely relieved by this plan of treatment.

When a tear is thus healed, when it makes neither immediate nor remote complaint, nor interferes with function, the wise practice, as it seems to me, is to let it alone. The old packing is removed and the new introduced once in four or five days during the interval between menstruation. It is very rare to find any offensive odor, provided sufficient iodoform has been used, even if the tampon has been worn a week.

Prior to the packing, in certain cases, it is advisable to paint the vaginal cervix with Churchill's tincture of iodine, or to apply the same medicine to the cavity of the neck or of the body of the womb: the indications for these local applications will be plain. Again, intra-pelvic exudates can be treated by painting the part of the vaginal vault corresponding with their position with the iodine preparation, and then applying either a glycerin or an iodoform tampon.

I have thus presented for your consideration cotton packing and the application of iodoform as a substitute for the ordinary pessary in certain cases of complicated retroversion. I commend it to the consideration of those who have never tried it, or of those who have not tried it efficiently and systematically, firmly believing that a faithful trial—faithful in all details and in continuance—of the practice will give them most satisfactory results.

There is another word to be said in favor of this plan of treatment. It is usual to state that certain forms of uterine pessaries do not interfere with marital rights. Marital rights are oftentimes in diseases of women marital wrongs, preventing or prolonging the cure, to the despair of the patients, if not to the reproach of medicine. Now, I believe that Dr. Taliaferro, in referring to the benefits of cotton packing, stated as one that it secured from sexual intercourse. That is true for the greater part of the month; but, as the packing is removed a day or two before menstruation, and a new one not made until three or four days after, intercourse at long intervals may occur, which possibly is better in some cases than

total abstinence, and certainly is better than frequency.

Let us pass now to the consideration of the tampon in obstetrics. Kormann,* whom I quote as the most recent author of a text-book upon obstetrics, observes that tamponing the vagina is indicated in dangerous hemorrhage from the genitals in pregnancy, in labor, and in childbed. In pregnancy it becomes necessary in the severe bleeding from abortion, or from placenta prævia; in labor, in hemorrhage from placenta prævia, or from ruptured varices, if the os uteri be not sufficiently dilated to permit the immediate ending of the labor, and in the after-birth period, the os uteri having again closed, an excessive anæmia forbidding immediate detachment of the placenta; and, after the labor is over, because of hemorrhage from a tear in the cervix, or from central placenta prævia.

Time will permit the consideration of the use of the tampon in only two of these conditions,—to wit, in abortion and in placenta prævia.

According to Charpentier,† in either of only two conditions is abortion inevitable: those are death of the embryo or fœtus, and rupture of the ovum; but in practice neither condition can be recognized in the majority of cases; we may in some have severe pain, more or less loss of blood, the cervical canal may be so dilated that the finger readily touches the ovum, and fragments of the decidua be discharged, and yet the pregnancy continue. Apart from prophylactic treatment of abortion, the dominant indication in grave cases is presented by the hemorrhage, and the two generally-accepted means for combating this blood-flow are ergot and the tampon. Now, both on theoretic grounds and from intelligent experience, many hold‡ that ergot, acting upon the muscular tissue of the uterus as a whole, tends to imprison as much as to expel the ovum, if given before dilatation of the canal or of the opening through which the ovum is to pass has been effected. But, on the other hand, a tampon properly applied, by pressing upon the neck of the uterus, and upon the lower uterine segment, in the majority of cases increases the energy and the frequency of uterine contractions, thus counteracting any injurious influence of the ergot. In serious hemorrhage, therefore, from abortion the combined use of these is wise practice.

While the primary effect of the tampon is to arrest the hemorrhage, and its secondary one to influence the uterine contractions, there are still two other effects to be attributed to it. Hindering or entirely preventing the escape of blood into the vagina, the tendency of the small quantity that may be poured out after it has been employed is to penetrate between the ovum and the uterus, detaching the former so that the abortion when it occurs is complete, no fragments of the membranes left behind to excite hemorrhage or by their decomposition to become a nidus for septic germs which thence may enter lymphatics or veins. Further, the tampon furnishes a support to the partially expelled ovum, whose walls are so thin, and therefore so easily ruptured, in the earlier weeks of pregnancy: here again we have a protection by the tampon from incomplete abortion.

In the application of the tampon in these circumstances a Sims speculum may be used; but I cannot regard it as essential, or indeed a speculum of any sort. Dr. Emmet has said, "It is impossible to tampon the vagina effectually without the aid of Sims's speculum." Now, there were heroes before Agamemnon, and poets before Homer. I cannot doubt that such men as Wigand and Holst, Dubois and Depaul, and countless others, effectually tamponed the vagina, though they did not use a Sims speculum.

The preparation for tamponing in abortion is first to have the requisite supply of cotton rolled in balls the size of a walnut, and then either have these dipped in a disinfectant solution, squeezing out the fluid, or—and I believe this would be better—have a small quantity of iodoform cotton to be applied directly over the mouth of the womb; next, have the vagina washed out with a two-per-cent. solution of carbolic acid. The patient now, lying upon her back, has her thighs separated, and the physician, having a position on her left side, standing or sitting as may be convenient, separates the labia with the thumb and forefinger of the left hand, or

* Lehrbuch der Geburtshülfe, Tübingen, 1884.

† Traité des Accouchements.

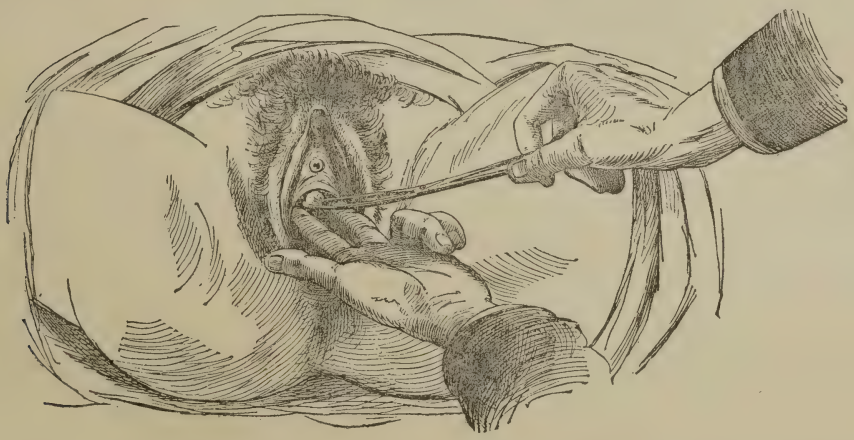
‡ For illustration, Benicke, rejecting ergot in abortion, has said that its use will cause such firm tonic contraction of the uterus that the introduction of one or more fingers is impossible (Zeitschrift für Geburtshülfe und Gynaekologie, 1878: Ueber die Anwendung des Mutterkorns in der Geburtshülfe).

with two fingers, thus holding the vulvo-vaginal orifice open; then, taking one of the tampons with the curved forceps held in the right hand, the cotton is carried up to the vaginal vault, and with the forceps or finger fixed in position, another mass is similarly placed, and thus the process continued until the vaginal vault is filled and the neck of the womb completely surrounded by firmly-packed cotton; next the mouth of the womb is to be covered, and then one or two more layers of the packing are placed immediately below, and thus probably one-third, or a little more, of the vagina is filled. It is not necessary to carry the packing into all the vagina: both Spiegelberg and Kleinwächter, in their well-known treatises, sustain this practice (Fig. 2).

I believe, then, that the proper treatment of inevitable abortion when the hemorrhage is serious is the combined use of ergot and a tampon to which iodoform is added; but I do not believe in the complete tamponing of the vagina, regarding it as unnecessary, nor in the addition of astringents to the tampon, for this is not only unnecessary, but often positively injurious.

Few subjects in practical obstetrics have given rise to more controversy than the use of the tampon in hemorrhage from placenta prævia. Some have claimed the highest value for the tampon, and are content to let the labor go on, provided the presentation is normal and the uterine contractions vigorous, no other means being used; others utterly reject the tampon, and still others use it temporarily,

Fig. 2.



So, too, it is unnecessary to add any astringent to the tampon; such medicine cannot come in contact with bleeding surfaces, but it does come in contact with the vagina, irritating it, causing its unneeded and injurious contraction: if one of the iron salts be used, the vaginal walls may be seriously inflamed. The essential idea in the use of a tampon for the arrest of hemorrhage is not the coagulation of blood, but compression. Most authorities, especially the German, direct that the tampon be left only a few hours in the vagina; but Charpentier says it should remain twenty-four, or, if necessary, thirty-six hours; and certainly, if the iodoform cotton be used, it might be left the longer period mentioned, or even twice as long, without any offensive odor in the discharge when the tampon is removed.

meeting a present indication, but only as a means to an end.

Baudelocque, nearly three-quarters of a century ago, announced the rule of obstetric practice in case of grave hemorrhage from placenta prævia: "The necessity of effecting delivery without having regard to the time of pregnancy, when the loss of blood is so abundant as to imperil the life of the mother and that of the child, has been recognized for more than two centuries."* And yet, if one consults Playfair's treatise on midwifery, referring to the part where the author considers the treatment of placenta prævia, he will see that this important rule of practice is regarded as quite recent in its enunciation.

* Traité des Accouchements.

Grave hemorrhage, then, it will be agreed, is an indication for prompt delivery: that is, deliver if you can. But suppose you cannot: what then? Here we must at once meet the flooding, which carries peril to both mother and child.

Such hemorrhage may occur either in pregnancy or in labor, though if in the former, labor is almost always thereby induced. Here it seems to me that the indication for the use of the tampon is plain, and all, I think, would agree to the wisdom of this practice did the accident occur in pregnancy. So far as the tampon in labor is concerned, the difference of opinion is very decided, two of the most distinguished obstetricians, for example, of this country, Dr. Ellwood Wilson and Dr. Albert H. Smith, rejecting it, I believe, absolutely. The reason for this rejection will be considered hereafter. Pajot and Bailly probably are the most eminent French obstetricians who are willing in certain cases to trust the labor entirely to the tampon. Among all who have in recent years sustained this practice, no one seems to have given proper credit to the distinguished obstetrician with whom it originated quite early in the present century, Wigand. In justice, therefore to him, and as explaining his method, let me quote from a paper* of his. Wigand, after stating that turning and *accouchement forcée* had been the practice generally received in cases of placenta prævia, and stating the serious dangers of such practice, observes, "These matters have been little considered: everything has been accepted as a sad, unavoidable necessity. So stood affairs when I, many years ago, desired and sought to find a better method. I was so fortunate as to find it, and often used it before the eyes of a great and intelligent public, and always with the most remarkable success. I wrote of it and urgently commended it (*im 3ten Hefte meiner Beiträge, Seite* 26, *und im Hamb. Magazin,* 11 *B.*, 2 *St.*, *S.* 107), and until now, so far as I know, *have not had a single follower.*† My method would not be favorably received by charlatan obstetricians,—this I foresaw,—for it is too simple and modest, and cannot, by a mere tampon plainly and gently introduced, produce the noise and sensation that another method has. But that so many sincere and conscientious practitioners, so far as commendation is concerned, have passed over it, and have not even considered the matter worth a trial, I can only explain by supposing that my writings have not come to their notice, or that they (God knows the cause) suspected I had not fully, truly, and correctly observed, drawing largely from my imagination. This suspicion I hope to remove by the present writing, which will sufficiently prove that I, with a large, honest, and industriously followed obstetric practice which kind Providence favored me with, surely did not need to worry myself to deceive and prevent observation, and urge a method drawn from imagination. It has been my earnest desire and great pleasure to learn not only what there was in books, but also to see clearly the writings and occurrences of nature," etc.

In describing his method, Wigand states that in the slighter hemorrhages from placenta prævia he simply directs mental and bodily rest, when the flow stops only gentle exercise being permitted, internal medicines being unnecessary, unless there are some obvious disorders to be corrected. "As soon as the first labor-pains begin, sometimes at the first occurrence of decided hemorrhage, I prepare a large tampon of soft linen, dipped in a thin oatmeal gruel; and the broad end, which is first passed into the vagina, is thickly covered with powdered gum arabic and rosin. The tampon is then introduced, so that it lies in the mouth of the womb, close to the already loosened part of the placenta. In order that the tampon may remain fixed and immovable in the same place, I further fill the vagina in all directions and in all crevices as firmly with linen or fine sponge as can be done without inconvenience to the patient. A thick napkin is closely applied over the genitals, and the parturient then lies upon her left side, with her thighs close together. I hold this position to be the most suitable, because then the placenta, not with its centre, but its border, first enters the vagina; for my observation has taught me that, as a rule, it is the right side of the placenta which is first loosened and comes out of the uterus." After referring to the diseased dynamic conditions of the womb which may occur, and which the physician

* I have taken these extracts from a volume entitled "Die Geburt des Menschen," etc., edited by Franz Carl Naegele, and published in 1820, three years after Wigand's death.

† But after his death he had many followers, and has yet. Some of them—Holst, for example—used a speculum in the introduction of the tampon.

discovering must endeavor to remove, etc., Wigand states that, should the patient after some hours complain of burning in the vagina, he takes out the tampon, replacing it by a fresh and smaller one. "But before the introduction of the latter I observe as to the following: Whether the mouth of the womb is considerably dilated, and whether the placenta has already begun to separate from one side or the other, usually the right. Whether the head or the feet, or some other part of the child, presents. Whether, especially at one side of the cervix, again generally the right side, the presenting bag of water is tense and elastic. And whether one can perceive that the presenting part of the child, as well as the separated border of the placenta, equally move down. If I find any other part of the child than the head, the feet, or the pelvis presenting, I proceed at once to turn the child, doing this with a much greater confidence, as the os is already softened and dilated, and the uterus has entered upon the birth-work and will complete my purpose.

"Once more, is the child's position normal, the configuration of the uterus good, the pains strong and efficient, the progression of the child decided, the tendency of the loosened placenta to place itself at the side of the vaginal wall plain,—if the patient's pulse is full and slow, her temperature good, or even, which is here especially desirable, she has a warm perspiration,—I leave the rest of the labor entirely to nature, which alone, sooner or later, by means of unusually rapid and powerful pains, will expel the living, healthy child, at the same time also the second small tampon, if such has been found necessary to introduce. The placenta was spontaneously expelled in all cases shortly after the birth of the child."

He subsequently remarks, "It must be sufficient for me to assure my reader that I have made use solely of this method in placenta prævia for many years, and have not lost a single child or mother, and, besides, have secured by it for the latter a completely normal lying-in. I do not deny that my method, like any other, has sometimes its own difficulties and complications. Thus, for instance, it cannot be applied with women whose birth-passage is so irritable that they cannot retain the tampon even for the space of fifty minutes; so, too, one would act very unreasonably, and even criminally, if he would use the method when called to a woman who had bled almost to death. But in so many other cases, and applied at the beginning of the labor or of the blood-flow, this method is and remains the most successful. And, even if nothing else shall be conceded to it, it cannot be denied that of all methods it is the most suitable and reliable to properly prepare for the operation of turning, if the latter has become necessary, facilitating it for the parturient and for the operator."

These quotations prove the priority of Wigand in the tampon treatment of placenta prævia, and also show the extraordinary success which attended this method in his practice. But it is also shown that he did not place exclusive reliance upon it, regarding it as suitable for all cases. To-day, I imagine, few practitioners would deny the value of the tampon or fail to use it in certain cases.

Those who object to its use rest their opposition chiefly upon the ground that thereby an open is converted into a concealed hemorrhage. I answer, not if the tampon be properly applied, and if careful pressure be made during a uterine contraction and just after, so that the portion of the tampon which is then forced from the vulva is pushed back, for there is then no space left between the uterus and the upper surface of the tampon, resulting from the recession of the former after contracting, in which the blood can accumulate. Possibly it would be well to have the bandage passing between the thighs—for after tamponing for the serious hemorrhage from placenta prævia the T-bandage is applied—made of elastic webbing or of rubber, and thus the same end be accomplished as is proposed by manual pressure.

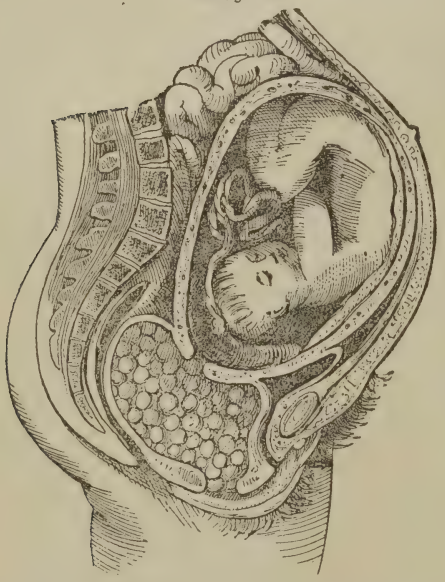
I have said that after a properly-applied tampon hemorrhage is arrested. How, for example, could any serious blood-flow, external or internal, occur when a tampon has been applied according to Dubois' method?

Depaul* has given the following description of that method, stating that he himself had followed it both in hospital and in private practice, and that it gave him excellent results. He directs about sixty balls of charpie, each about the size of a pullet's egg, to be prepared. A thread is

* Leçons de Clinique obstétricale.

attached to the first twelve that are introduced, then these are coated, as the others, with cerate, both to facilitate their introduction and so they may form a more compact mass, less easily penetrable by the blood, and insinuating themselves more readily in the vaginal cul-de-sacs. "I do not use a speculum in order to introduce them, since I regard this instrument as useless, if not injurious, for often its introduction causes an increase in the flow. I place in the vagina the index finger of my left hand, and, introducing with my right hand a ball of charpie having a string, the index of the left hand passes it up in the posterior cul-de-sac and keeps it in place. A second ball is similarly introduced and put by its side; then in turn a third is introduced,

FIG. 3.



and thus on, until the vagina is completely filled, and even distended. Two pieces of charpie are placed in the vulval orifice, and over these a square compress, and a T-bandage is used to keep all in place" (Fig. 3).

While it is possible to tampon effectually, as is to be seen from the extract just read, without the use of a speculum, yet this will be facilitated if one has the instrument of Sims or of Simon in the operation. But in either case, as in the tamponing for abortion, astringents are unnecessary, but an antiseptic is always to be remembered.

It must be admitted that the tendency of obstetricians has been in recent years to the rejection of the tampon. Kleinwächter,* for example, asserts that tamponing the vagina in hemorrhage from placenta prævia is irrational. Probably the just appreciation of the tampon in placenta prævia has been given by Müller in his well-known work:† "We draw from these studies the correct conclusion as to the action of the tampon. It is not to be looked upon as a sovereign remedy, as its friends claim, nor to be excluded from therapeutic means, as its opponents desire. The tampon is an important aid, but, like many others, only in the hands of those who can properly apply it. Use it at the right time, and then no longer than is necessary. Apply it when the mouth of the womb is rigid and slightly open, if violent hemorrhage occurs, for immediate delivery is impossible. You can by it gain time without danger, for, even if it does not stop, it lessens the bleeding and prepares the yet unprepared birth-parts for labor."

It is foreign to the purpose to speak of other methods of treating placenta prævia, or I might refer to those of Puzos, Simpson, Barnes, Cohen, and others, and speak of the success of Dr. Davis, of Wilkesbarre, by a modified Cohen method, and of the more recent extraordinary successes of Hoffmeier and of Behm, though really those successes are no better as to maternal mortality, and very much worse as to fœtal mortality, than Wigand claimed by his method.

May the day come when in regard to this, and to all other great questions of therapeutics, there shall be common consent as to the rules followed! "So runs my dream." But whether it came out of the horn gate or out of the ivory gate I do not know: time will tell.

1902 CHESTNUT STREET, PHILADELPHIA.

SULPHIDE OF CARBON AS A DISINFECTANT.—After a review of the subject at the request of the Prefect of Police, Dr. Dujardin-Beaumetz recommends burning sulphide of carbon in an apparatus constructed for the purpose in the locality where a cholera-patient has been lying. Burning sulphur is the best disinfectant, but there is also a danger of burning the house in careless hands.

REPORT ON THE PROGRESS OF GENERAL PATHOLOGY AND CLINICAL MEDICINE.

BY JAMES C. WILSON, M.D.,

Physician to the Philadelphia Hospital and the Hospital of the Jefferson College.

ON INFLUENZA.

THE obscurity of the exciting cause of influenza has baffled observers from the earliest records to the present times. The resultant of the combined labors of all investigators has been simply the negative proposition that it is not any of the many things that it has been from time to time suspected to be. On the principle of exclusion the disease has been referred to miasmatic origin, and in accordance with our present views such a cause must be an organized germ,—*miasma vivum.* Upon no other hypothesis can the pandemics that have at longer or shorter intervals overrun the greater part of the earth's surface be explained. Notwithstanding the general acceptance of the theory of a living cause, even the late epidemics have afforded no actual proofs of its existence. Kormann, in a recent monograph on influenza, predicted that, with improved methods of investigation and a far greater knowledge of the natural history of microphytes than heretofore, we were in a position to recognize this miasm in the next epidemic that appeared. This certainly has seemed most probable to those who accept the parasitic theory of the infectious diseases, and who believe that the specific exciting causes of tuberculosis, pneumonia, erysipelas, enteric fever, malaria, cerebrospinal fever, and other infectious diseases have already been discovered and isolated. Whilst the great mass of scientific medical men hesitate to accept in their entirety the radical views of the German school, simply because much of the material upon which these views are based is not yet fully worked out, it is apparent that the work already done is having its influence, and that the drift of opinion is strongly towards the acceptance of the germ theory of disease, not in its original bearing, but in a far wider and more comprehensive sense.

Dr. Otto Seifert studied influenza in a limited epidemic that occurred in Würzburg during the winter and spring of 1883, with great minuteness and painstaking, with a view of clearing up some of the still uncertain points in its symptomatology, and more especially with reference to its exciting cause. He has published the results of this work in *Volkmann's Klinische Vorträge* (No. 240, June 20, 1884). The epidemic did not present in all respects the characters usually manifested by unquestionable influenza. It was a localized outbreak, and was associated with a grave epidemic of measles in the beginning, and with a very general outbreak of whooping-cough towards its close. Nevertheless, Dr. Seifert, who saw seven cases in hospital and three in his private practice, and who heard of others from his colleagues, was satisfied of the nature of the affection, which conformed in many particulars to the ordinary clinical descriptions of influenza. First, of the fever: This showed a gradual ascent, with morning remissions, like that of typical enteric fever, to a maximum of 38.8° or 39.5 C. on the third or fourth day. The decline, beginning at once, was critical, and occupied two days or at most a part only of the third day also. After this the temperature-wave was irregular.

The spleen was in some of the cases enlarged, an observation in accord with that of the majority of observers, and thought to be of importance in view of the difficulties of diagnosis between influenza and enteric fever and intermittents. For my own part, I believe these difficulties can only occur under the most exceptional circumstances. It is not probable that a hesitancy to make a diagnosis could arise in either case except at the beginning of the attack, and the presence or absence of slight enlargement of the spleen would not be of sufficient diagnostic importance to decide any doubtful case.

Dr. Seifert's most important investigations were those bearing upon the etiology of the disease. He found in the mucus expectorated great numbers of micrococci, which measured 1.5 to 2.0 μ in length and 1.0 μ in breadth (magnified 350 diameters). They at no point occupied any definite relation to the pus-cells, and were situated neither within nor upon them. They were arranged in chains, or in pairs, or scattered singly. They were found in the sputa and nasal secretion of all the cases, but were not found in the secretion of the conjunctival sac, nor in the blood. They were not found in the sputa of the ordinary cases of other forms of bronchial and pul-

monary catarrh. They were best colored by methyl violet. The inoculation of two guinea-pigs was not followed by the symptoms of influenza. Culture-experiments were not carried out. Dr. Seifert proposes to call this microphyte the influenza-coccus.

Our judgment upon this subject must be held in abeyance until further researches in unquestioned influenza epidemics are made, and until the peculiar coccus, if found, shall have been cultivated and tested by inoculation experiments.

In view of the parasitic nature of the cause of influenza, and its apparent restriction to the mucous membranes of the naso-bronchial tract, Dr. Seifert suggests, in addition to the usual symptomatic treatment, direct local measures. These may consist of nasal douches of such disinfectant solutions as are least liable to irritate the tissues, and in the inhalation of like substances.

SPIRILLUM.

Dr. F. A. Mülhaüser, of Speier, has contributed to *Virchow's Archiv* (July 9, 1884) an elaborate paper upon this genus of microphytes. His researches have resulted in a wide extension of the general knowledge of the subject, and especially in reference to its relation to relapsing fever (Rückfallstyphus).

Spirilla are microscopical bodies of the form of a spiral, and with the property of spontaneous movement. They have been long known, and were described and delineated by Ehrenberg, Dujardin, Pritchard, and others, and have been quite recently made the subject of close investigation by Cohn, of Breslau. On account of their capacity of free and lively movement, they were referred by the earlier observers to the Infusoria. Recent investigators look upon them as low plant-forms. They have been found by chance in fluids of various kinds. There has been, however, neither sure way of finding them nor definite place in which to look for them. Therefore these delicate, quick-moving little organisms long continued to be regarded chiefly as curiosities of microscopical research.

The peculiarity of their form and the liveliness of their movement have excited a great interest in all who have observed them, and but for the difficulty in discovering their habitat they would have long ago become a favorite object of microscopical study. In 1873, Obermeier made the remarkable discovery of spirilla in the blood of patients suffering from relapsing fever. These resembled in all respects those previously seen under other circumstances. Owing, however, to the difficulties of the whole subject, very little advance has been made until the present time in our knowledge of these parasitic microphytes. The success of H. Vandyke Carter in cultivating spirilla in the blood of monkeys by means of the inoculation of the blood of relapsing-fever patients is well known. Cases of relapsing fever, fortunately, are rare and transient. Dr. Mülhaüser complains—purely from the stand-point of the microscopist, I trust—that epidemics of this disease have not yet occurred in South Germany. Notwithstanding this fact, his researches have been bountifully rewarded, and he has discovered a locality in which spirilla are to be found at all times and in abundance. He found on one occasion in the stool of an enteric-fever patient, after it had stood a long time, a number of spirilla of large size (Spir. volutans). Further investigations in the same direction, it is true, failed. But the field of investigation was extended so as to include various putrefying fluids. At length spirilla were found in the water of a vase of flowers. Foul infusions or macerations of the most varying mixtures of both animal and vegetable substances, bog-water, drain-water, mucus, fæces, contained other microphytes of various kinds, but in most instances no spirilla.

Finally, in the places where the discharges of the domestic animals are collected, namely, dung-heaps, spirilla were found in abundance. The oozing fluid of such places contains everywhere, and at all seasons of the year, these little organisms in such numbers that they appear to be an essential product of the processes going on in it. It contains that form of spirillum which appears to resemble most nearly the spirillum of relapsing fever, and that form only.

Those interested in following the author's description of the development of spirilla, of their various forms, and his lucid account of their movements, their striving after oxygen, and other matters of their natural history, which is indeed wonderful, are referred to the original. I quote briefly some statements which are of peculiar interest to physicians:

Fully-developed, long spirilla live usually during only a single day, and it is the result of a most wonderful chance that Dr. Obermeier came upon them in this short period in the blood of patients. They are the cause of relapsing fever, and not accidental appearances, not *épiphénomènes*, as Lewis believed.

Relapsing fever constitutes an experiment by which is determined the length of time required for the development of the spirilla and the influence of warmth and albuminate. Rühle (1883) stated that observations under the microscope showed that the fully-developed spirilla reappeared in the "moist chamber" at the same time as in the blood of the patient. At the height of the primary attack the long spirochæte fall to pieces, forming the seed of new spirochæte, which on the seventh day of the intermission are full-grown, and this process repeats itself until the death or convalescence of the patient. It is not the high temperature, as Heidenreich believes, that causes their destruction, but their age. This refutes the view of Lewis and Murchison that the spirilla are the result and not the cause of the fever. The more contagious a disease, the finer and more movable its spores. Mülhaüser believes that the spores of the spirochæte of relapsing fever are so minute that, borne in the air, they enter the body by the air-passages or by contact with the skin, and thus in susceptible persons produce the disease.

In this connection, the following remarks, published in 1881 in an article on Relapsing Fever,* are not wholly without interest:

"The conclusion that this parasite has to do with the causation and development of relapsing fever is inevitable. It constitutes the contagium. The spores of these spiral filaments, communicated from individual to individual, spread the disease. Finding in the human body the conditions favorable to their development, they multiply indefinitely. The functional perturbations to which their presence gives rise constitute the phenomena of the fever. It is probable that, under favorable circumstances outside the body, their existence may be prolonged through a considerable length of time. This existence may be latent, yet capable of assuming the most energetic activity when introduced into the human body. Such being the case, the possibility of transmission to remote points follows, and the rise of epidemics at considerable intervals of time and at points far distant from each other is comprehensible without the assumption of the independent origin of the germs of disease, or the new development of an old poison. It is much more in accordance with the general laws of nature to accept a continuous concealed existence of the germs than to have recourse to spontaneous generation to account for their development.

"The origin of an epidemic is due to the importation of the *materies morbi* in the person and belongings of a patient, or in other materials from an infected locality, *or else to circumstances calling into activity germs that have maintained a latent and harmless existence during a more or less extended lapse of time.* The history of relapsing fever in all great epidemics points to scarcity of food and its attendant evils as the conditions favoring the activity of relapsing-fever germs.

"When the disease has appeared in any locality it spreads with great rapidity by contagion, but in every community it forms centres of greatest prevalence. *These foci are determined by the dense crowding together of the poor in the most wretched quarters of cities, and by impure drinking-water and stagnant water in the neighborhood of dwelling-houses.*"

THE ETIOLOGY OF PHTHISIS.

It is certainly a striking fact that in two instances within as many months earnest protests against the too-ready acceptance of the conclusions drawn from the discovery of the bacillus tuberculosis have been published in Berlin. In *Virchow's Archiv* for June 6, 1884, Wargunin, of St. Petersburg, called a halt, and urged upon the profession the importance of hesitancy in accepting views so radical and as yet unreconciled to universal clinical experience. The theory of Koch calls up a host of questions which, in its present phase, it is inadequate to answer. This protest is based upon an elaborate study of the lesions produced in the lungs of dogs compelled to inhale repeatedly (*a*) the pulverized fresh sputum of phthisical persons, (*b*) the same disinfected, and (*c*) the sputum from a patient suffering from emphysema,

* The Continued Fevers. By James C. Wilson. New York, 1881.

and mixtures of cheese and of meal. The result was in all these experiments the same,—the production in the lungs of disseminated lesions of exactly the same kind, having the macroscopic characters of tubercles. Histologically, however, the process was essentially a lobular broncho-pneumonia, resembling the desquamatic pneumonia of Buhl, and etiologically to be classed in the category of pneumonias due to the inhalation of foreign substances. It is true that the bacillus was not found, for the announcement of its discovery was made just as Wargunin's researches were concluded, and it was not sought for. Nevertheless, that those disseminated lesions were not tubercular may be assumed from the fact that all the dogs thus treated, which were afterwards placed under good hygienic conditions and allowed to live, fully recovered, and in two of them that were killed for examination after a period of six months the lungs were found in an entirely normal state. In none of the dogs subjected to these experiments were there evidences of any general disease.

Dr. P. Langerhans, of Madeira, contributes to the same journal for August 5, 1884, a paper which is of interest as embodying the results of observations bearing upon the positive influence of heredity in the etiology of phthisis on the one hand, and the negative influence of such exposure as is peculiarly favorable to the spread of diseases by contagion on the other. These observations, conducted with much painstaking, and in a singularly circumscribed locality, the island of Madeira, and in particular its capital, Funchal, and its immediate surroundings, are worthy of a more extended notice than the present space at my disposal permits. Koch demonstrated that the bacillus caused acute miliary tuberculosis. The bacillus is thus the virus of acute miliary tuberculosis. But neither Koch nor any other of the many experimenters who have performed inoculation with the bacilli and with tubercular débris have succeeded in bringing about a process which bears the most remote resemblance to chronic pulmonary phthisis. The bacillus is, it is true, present here, and often in abundance. But its presence by no means determines its causative relation to the primary lesions, nor even, in the absence of further evidence, to the secondary lesions of this complex lung-affection.

The objections to the theory of Koch appear to Dr. Langenhans so well founded that they deserve the most earnest consideration, especially in view of the present "bacillus enthusiasm." Two methods of observation must yet be worked out.

First, the examination of the lesions in the early stages of phthisis; second, the critical study of all possible etiological factors. His paper is a contribution to the second of these methods.

In the limited colony of foreigners at Madeira he has had the opportunity of tracing out from registers and other information the personal history of 267 persons, resident on the island in the year 1836, when the necessary data were for the first time preserved. Of these, 210 were in good health and had no traceable hereditary predisposition; 57 were members of families who had settled upon the island on account of pulmonary diseases.

Of the 210 healthy persons, 86 were still living at the date of the writing of the paper; 124 deceased; 4 had died of phthisis; none of those still living suffered from that disease.

Of the 57 consumptive or predisposed persons, 5 were in 1836 under 10 years of age. Of these 5, none died under the age of 20 years; 35 are deceased, 9 of them of phthisis.

A second group consists of persons who came to Madeira after the year 1836 and before the year 1864, and whose stay upon the island continued till death or extended over a period of at least twenty years. This group numbered 115. Of this number 83 were sound, 32 consumptive or predisposed.

Of the 83 sound persons, 31 were at the date of writing deceased,—none in consequence of phthisis,—and not one among those still living presented any sign of that disease. Of the 32 consumptive or predisposed persons, 22 have come upon the island suffering from established phthisis, 10 merely predisposed by descent. Of the 22 already ill, 12 died of the disease,—7 at Madeira, 5 elsewhere; 5 died of other affections, making in all 17 deceased. Of the 10 merely predisposed, none have developed the disease. A third group is of especial interest. It comprises the children of the 267 residents in 1836, and of the 115 later comers, numbering 253. Of this number 147 were healthy, 106 consumptive or predisposed. Of the 147, 28

have died,—1 of phthisis; of 119 still living, none have phthisis; of the 106, 23 have died,—8 of phthisis; and of 83 still living, 8 were known to suffer from phthisis.

Of 635 persons thus far, 440 were sound, 195 consumptive or predisposed.

Of 440 sound, 203 are deceased,—5 of phthisis; 237 are yet living and free from phthisis.

Of 195 not free from taint, 75 are deceased,—29 of phthisis; and of 120 still living, 12 suffer from the disease.

These figures are subject to the errors which affect such statistics everywhere; but the elaborate tables and analyses of Dr. Langenhans certainly amount to evidence of great importance as to the influence of heredity.

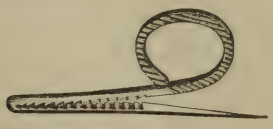
On the other hand, the life on the island has been extremely favorable for the spread of phthisis by contagion, if such had been its method of extension. The sick and the well live in this community, as everywhere, in the closest association, occupying the same houses and the same rooms, using the same furniture and utensils.

In conclusion, it is proved by actual case-histories that in the health-colony at Madeira, since 1836, those individuals only, almost without exception, have contracted phthisis in whom there existed a hereditary predisposition, although the different constituents of the colony were exposed in precisely the same way to the same favorable conditions for infection.

NEW INVENTIONS.

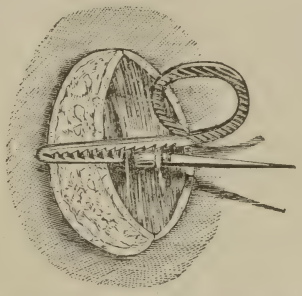
AN ARTERY-COMPRESSOR.

A CONVENIENT and effective appliance has been devised by Dr. Levis for the rapid arrest of hemorrhage in large open wounds. It is exceedingly simple and inexpensive.



Numbers of the compressors can be quickly applied during an operation, and the surgeon may leisurely ligate the vessels if, after their removal, the ligature should be required. In many operations, attended for the time by great hemorrhage from numerous small vessels, the temporary stasis produced by the compressors will be sufficient to prevent further flow.

By this device the operator can proceed to the end of an operation without stopping to apply ligatures.



The instrument and its application are so illustrated in the cuts that description is unnecessary.

The compressors are made by Snowden, 7 South Eleventh Street, Philadelphia.

NOTES OF HOSPITAL PRACTICE.

MEDICO-CHIRURGICAL COLLEGE.

CLINICAL SERVICE OF JAMES E. GARRETSON, M.D., PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY.

SURGICAL TREATMENT OF NEURALGIA.

TO-DAY, gentlemen, I am to bring before you four patients illustrative of extremes in the surgical treatment of a condition known to the general public as neuralgia.

As the hour will be fully occupied in the operations to be performed, I shall enter into no discussion as to the multitude of causes out of which nerve-pain arises and in which it exists, but will proceed at once with what is to be done, suggesting, parenthetically, that science applied to the treatment of neuralgia means knowledge directed to appreciation of relationship between cause and effect. Pain is intangible: it is not to be seen, tasted, touched, or heard; it is not substantive; it is phenomenal; neuralgia is not principal.

Case I.—The young gentleman now introduced is a professional *confrère*. For three years he has been a martyr to facial pain of an excruciating character, the region affected being the infra-orbital. During these three years the sufferer has been my patient, and during these years I have

exerted myself to get understanding of the lesion which holds the meaning of the pain, and which, whatever it may be, is to be removed as making our only road by which pain may follow. I stand before you this hour confessedly ignorant of the cause of the man's pain; to me it has proved beyond finding out.

What is to be done with effects of this character where causes cannot be discovered? How many are the experiences suggested to the recollection of every practitioner by the query!

Facial neuralgia is at times of a character that is simply unbearable. Something has to be done. The something is anything that will afford ease. A present good is discounted at the expense of a future ill. You object to what you do, yet do it. You disclaim, but perform.

Now, if there be one class of men which, beyond all others, should avoid the use of morphia, it is the student class. Here in my hand is a hypodermic syringe. It is charged with one-quarter grain of morphiæ sulphas, dissolved in eight drops of water. Because that the patient cannot endure his pain, and because, truthfully, I know not how else to relieve him, I am going to place this morphia beneath his skin. Objecting as I do to the use of any opium preparation, you are to accept that in the present, as in any of my cases, I resort to the drug only when pushed to the wall. For months I relieved our friend here by the nightly use of a Volta's pile bound over the paining part; indeed, the relief continued so long that we were both congratulating ourselves on having come to a cure. On failure of the pile, Blaud's pills were used, in doses of fifteen grains of the dried ferri sulphas, and the same quantity of carbonate of potash daily. Apropos, let me say that in cases of the unexplainable neuralgias no single remedy has proved so useful as these pills. My prescription is as follows:

℞ Ferri sulphatis exsic.,
Potassii carbonatis, āā gr. ccl.;
Syr. acaciæ, q. s.—M.
Ft. pil. no. 100.
Sig.—Begin with three a day, and increase to six; take several hundred.

A remedy that not infrequently proves serviceable in paroxysmal neuralgia is Duquesnil's preparation of aconitia, in doses of gr. $\frac{1}{200}$, repeated each two hours until numbness is felt; but in this case it did no good.

Brown-Séquard's somewhat famous pill amounts generally to nothing: here it was tried faithfully by the patient on his own prescription.

A local application commonly of great use, but here yielding no result, is a combination devised by Dr. J. L. Ludlow:

℞ Atropinæ sulphatis, gr. ss;
Aconitinæ, gr. iss;
Olei tiglii, gtt. ii;
Ung. petrolii, ʒii.—M.

Not to delay, it may simply be added that I have looked this patient all over in search after cause, and have, as yet, failed to find it. I have treated him tentatively with every medicine in which lay hope of doing good, yet have secured no cure. It is to be the contents of this syringe, gentlemen, or it is to be agony. The former seems to me to be the smaller of the two evils: so I choose it.

In employing medicaments hypodermically, attention is to be directed to the avoidance of throwing the fluid into a vessel, also to the prevention of abscess. In the first matter knowledge of anatomy and the sense of sight are to be used. In the second, care is taken to avoid rupture of the cellular tissue, an accident which happens alone to the physician who is in too great hurry to get through the operation.

Standing over the patient, I introduce the needle by the side of the nose. The syringe, as you see, occupies an inverted position. I force the piston a trifle, but depend partly on gravity to get the morphia deposited. I break no cells, and will have no abscess.

Case II.—The second case is this robust colored man. His trouble is sciatica; that is to say, he has neuralgia, or nerve-pain, in the sciatic region. The cause here is rheumatism. To afford immediate comfort to the patient, I charge a syringe with eight drops of chloroform and introduce the needle its full length into the muscles of the ilio-femoral crease. "Does the injection burn?" we ask him. His reply is, "Not particularly."* In two days this application will be repeated, while at once the man will be put on the use of strong lemonade.

Here a very practical experience is to be kept in memory: hypodermic injection of chloroform, while affording relief from

* In half an hour the man was entirely free of pain, from which he had been suffering for two weeks.

neuralgia as the sciatic region is affected, acts exactly conversely when used about the face.

Case III.—The patient before us is, as you see, a delicate woman. The neuralgia here is of long standing, and confines itself to the region furnished by the temporal branches of the auriculo-temporal nerve. A peculiarity is the continued manifestation of vascular disturbance limited to the immediate locality. The intention in the case is to ligate the temporal artery and to exsect the auriculo-temporal nerve.

To do either, or both, of these operations, I will commence by making a vertical incision along the front of the ear, reaching, below, as far as the zygoma. The vessel lies under, or rather in, the temporal aponeurosis, and to reach it safely a director is wisely employed. [The artery, having been exposed, was then ligatured.—REP.]

The vessel being now taken care of, I search for the nerve. No difficulty is experienced, you see, in finding it: I show it raised upon the hook. I now dissect out a portion and cut it off. The wound will be put up to unite by first intention.

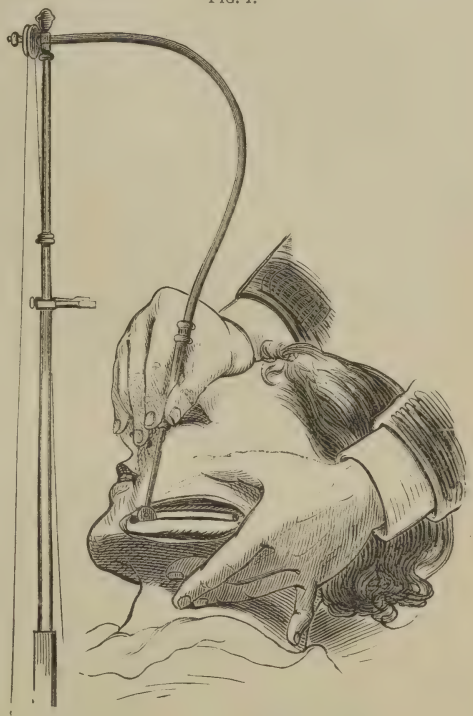
Case IV.—The present case is to show an extreme as to operations for nerve-lesions. The affection here is disease of the inferior maxillary nerve and of its mylo-hyoid branch. The performance proposed is exsection of the root of the nerve where it issues, at the base of the skull, from the oval foramen.

The manipulations to be practised will worthily command your close observation. The intention is to show how, by means of instrumentation, complexity is resolvable into simplicity. I am to show that the foramen ovale is to be reached without making observable scar upon the face, and without disturbing the integrity of the lower jaw.

Several years back, having occasion to exsect the inferior maxillary nerve for a refined and very handsome young lady, I was urged by recognition of the deforming scar left by the usual operation to set to work to devise a better. What grew out of the study is shown in the plate handed around (Fig. 1). A glance at the diagram by the surgeons who favor me with their presence this morning will, I am sure, render either description or commendation unnecessary. I do not hesitate to say that I think it will be long before the device is improved upon. The incision seen, it is to be understood, when healed, is in the shade-line below the jaw.

Fig. 2 shows a second operation belonging to the surgery of the region, which I devised and practise for securing section of the same nerve where it emerges from the skull into the zygomatic fossa. This

FIG. 1.



is the performance I am now to execute in your presence.

The patient, the gentleman just brought in, is a great sufferer from persistent neuralgia, related with the inferior maxillary nerve and with its mylo-hyoid branch. He can neither talk nor eat with comfort. He describes his life as made by this pain altogether miserable. He is one of a class which asks itself, not without a show of philosophic reason, "Is life worth living?"

The resolution of philosophic conundrums of this class lies always with knowledge. All that is needed is to know how to change the aspect of a condition. Luckily, as the present case is concerned, wisdom abounds in this clinic. We have learned that the man's neuralgia relates with a diseased nerve, and we know how to rid the sufferer of the nerve.

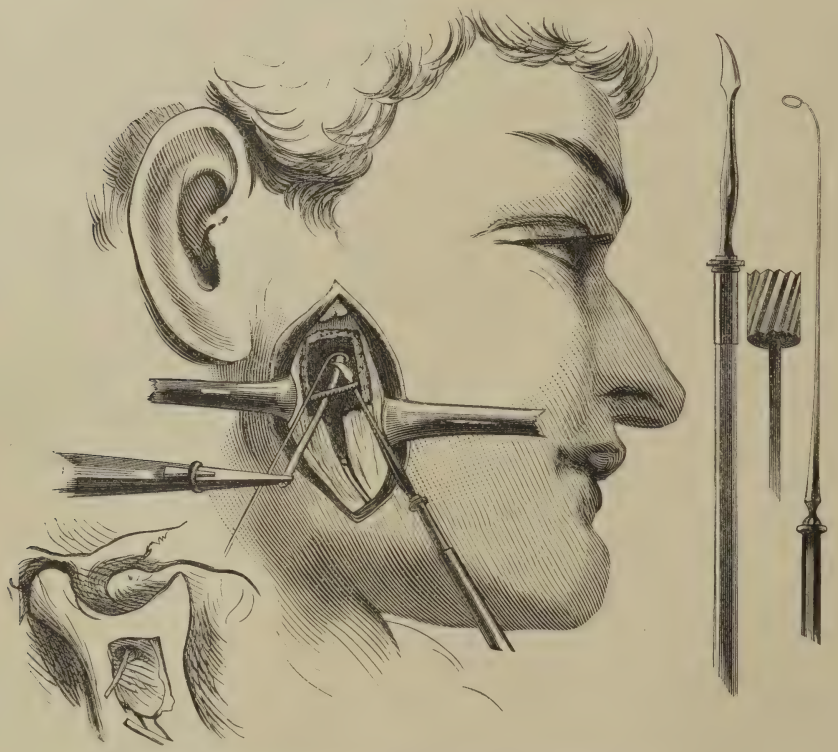
You understand that it is the intention

*

to expose the situation of the oval foramen and to excise the nerve. The patient being etherized, I commence with an incision which begins an inch above the angle of the jaw and which is carried downward and forward to the length of an inch in front of it, this cut being in the shade-line below the bone, which shade-line, to avoid injury to important parts covered by it, is pulled upward upon the jaw and thus incised. Ligation of the facial artery is commonly made necessary as a result of this first step. . . . It is

Here I introduce the surgical engine. The meaning of this machine is to revolve cutting instruments. I show you (held in my fingers) a burr. This burr is unimportant-looking, but when in revolution ten thousand times to the minute you may trust it to make a hole through the front of a brick house. A burr running ten thousand times to a minute shows no motion, but I would not advise you to trust its quietude. Here the intention is to cut into the face of the maxilla until the canal is opened and the nerve exposed. This I

FIG. 2.



The artery in the diagram should be placed higher: it crosses the sigmoid notch.

required in the present instance, as the spurting vessel makes evident.

Hemorrhage controlled, retractors are introduced, as here done, and the lips of the wound separated. Now is exposed, as all see, the periosteum-covered bone. A succeeding step uses the raspatory, which quickly denudes the part of a limited portion of its covering. I ask you to observe the extent of the part uncovered. It is not great,—sufficient simply to make ready for that which is now to follow.

proceed to do. . . . A single minute has, as you remark, sufficed to accomplish it.

Next, I pick up the nerve, and, cutting it in twain, I grasp the end next the brain in the teeth of the bull-dog forceps. Lifting it by means of this convenience, I follow upward with the burr until, as now I feel, I am at the situation of the posterior dental foramen. This foramen it is the intention and purpose to enlarge (see Fig. 2). With the instrumental means possessed, no difficulty is experienced in doing

this. True, a steady hand, acquaintance with the anatomy of the part, and a knowledge of the instrument you handle are not unimportant addenda; but, as you perceive by the present easy going on of the process, there is nothing at all difficult or complicated in the performance; perhaps, however, there is a little in "the know how."

The nerve being now firmly in the grasp of the forceps, and an opening of sufficient size being made in the ramus of the jaw, attention is to be given to a hemorrhage which you recognize as coming, not from the internal maxillary artery, but from the inferior dental. I have simply to pick out the vessel and to cast a ligature about it.

The audience is now to observe that I can pass a fenestra about this nerve, and that I can touch with the projected instrument the oval foramen. (Dr. Janney, the ex-coroner, who sat close to the operator, was asked to repeat the operation, which he did, passing the instrument the length of the zygomatic fossa.) Now, what I need to complete the operation after a high scientific method is a delicate guillotine, which Mr. Kolbe is engaged in making for me after a pattern, but which, not being ready, I duplicate with a tenotome, an instrument dangerous to use by reason of the presence of the internal maxillary artery, which, as is to be remembered, passes from the carotid externus immediately across the head of the jaw and is inconveniently in the way of a sharp blade.

I show you, gentlemen, the incised nerve. The operation is done.*

TRANSLATIONS.

Parenchymatous Injections of Turpentine in Malignant Growths.—From a series of injections of turpentine into the interior of malignant growths in order to influence their development, Dr. Vogt reports (communications from the Chirurgical Clinic in Greifswald) as follows: The first case was a return after extirpation of a carcinomatous breast, which showed itself as a rapidly-growing tumor pressing forward from the anterior mediastinum. One-half of a Pravaz syringeful of a solution of equal parts of alcohol and oil of turpentine was injected. In a few hours there was severe pain, fever, and erysipelatous redness of the breast. After forty-eight hours the temperature declined, but the general malaise lasted several days longer; the tumor had become visibly contracted. In ten days a second injection was made, with the same effect at first, but afterwards an abscess formed. Two more injections were made during the next few weeks. In the course of two months a gradual shrinkage of the tumor took place, which then remained as a decidedly hard tumor without any abnormal heat. The patient was then discharged.

The second case was one of multiple sarcoma, which was treated in the same way, with the same results, including the abscess. In the course of five weeks, after repeated injections, the tumor had almost disappeared.—*Centralblatt für Chirurgie*, No. 36.

Salicylic Acid as a Prophylactic against Cholera.—Dr. Beaudon, in a letter to the *Bulletin Général de Thérapeutique* (August 30), recommends the systematic use of salicylic acid as a prophylactic agent in case of a cholera visitation. He proposes a five-per-cent. alcoholic solution, of which a teaspoonful is to be added to a glass of water: with this the hands and the mouth are to be washed two or three times daily. This precaution should be especially exercised by medical men, who, in case of epidemic, are called upon to expose themselves to the contagion. A teaspoonful might also be taken, in water, with the meals. This method, if it does not destroy the microbes, will at least put the patient in a condition less favorable for their development.

Cauterization of the Wounds made by Rabid Animals.—In commenting on the report of a case of rabies, Dr. Dujardin-Beaumetz endorsed the following recommendation of the Conseil d'Hygiène Publique contained in a publication in 1882:

"The cauterization should be made with Vienna paste, chloride of zinc, butter of antimony, and especially with the hot iron, which in such cases is the best of the caustics. On the contrary, the use of ammonia, the different alcohols, tincture of arnica, and carbolized solutions is absolutely inefficacious."—*La France Médicale*, No. 106.

* The operation was done on September 6. The relief continues perfect up to the date of this issue, October 4.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, OCTOBER 4, 1884.

EDITORIAL.

VOLUME XV.

THE PHILADELPHIA MEDICAL TIMES, with this issue, begins a new volume. During its fourteen years of continuous publication it has achieved a success which is substantial and real, and established a bond of unity with the profession that enables its management to speak with reasonable assurance as regards its future. The progress that has been already made, it is believed, represents a permanent gain, and from the present advanced standard we expect to triangulate forward, as Dr. Holmes happily puts it, over fields yet to be occupied, and thus acquire new elements of value. The reviews of progress in various departments of medicine, introduced last year, have been well received by our readers, and will be continued; the correspondence, both domestic and foreign, will be extended, and prompt attention will be given to current events in medical circles and medical societies.

The fact that contributors to the *Times* are remunerated for their articles by the publishers at the highest rates paid by medical journals enables the editor to make a selection, and to accept those only which are deemed most valuable. In this respect the volume published during the last year, certainly, compares favorably with other volumes which have gone before.

Finally, the action of the publishers in reducing the subscription to one-half the price of last year deserves especial mention, as we think it will tend to increase the popularity of the *Times* and extend its influence with the profession.

The *Times* being a bi-weekly, it is enabled to record the progress of medical art with more deliberation and discernment than if it possessed a more ephemeral character. In conclusion, we ask the attention of our readers to the literary as well as the scientific merit of its contents, and to the mechanical execution and press-work, which will be always kept at the highest attainable standard.

MYCOLOGY IN OLD CLOTHES.

TRUTH is universal, and the language in which it is clothed is an accident of time and place. Hence literature abounds in thoughts so alike and expressed in terms so similar that it sometimes seems literally true that there is no new thing under the sun. Even the latest work of science, in fields wide and strange as any that knowledge yet has reached, often finds some suggestion in the writings of antiquity so apt that it seems like the forgotten record of old truths that are new only to us.

The Greek historian Eratosthenes (275–194 B.C.), according to Strabo (66 B.C.–24 A.D.), held with the Homeric school that the three continents of the Old World constituted a connected island, around which flowed the great sea, Oceanus. But he added in his account that there was doubtless another great world-island, or even several, in the farthest regions of the earth. To this Strabo adds that if this indeed were the case the creatures found in such new worlds would be different from those in the old. When we reflect upon these statements in connection with the discovery of the American and Australian continents, they seem indeed prophetic. Prophecy has many a time gone wider of the mark.

Not less remarkable is a passage that occurs in the writings of M. Terentius Varro (116–27 B.C.). This writer, described as encyclopædic and prolific, contributed much to an exact knowledge of Italy, his native land. In the first of his

three books "De Re Rustica" is to be found the following modern view in an ancient garb: "Si qua erunt loca palustria crescunt animalia quædam minuta, quæ non possunt oculi consequi, et per aëra intus in corpus per os et nares perveniunt atque efficiunt difficiles morbos." Who does not recognize in this description the Bacillus malariæ? Dr. Kotelmann, of Hamburg, to whose erudition the citation of this passage at the present time is due, points out the curious correspondence between it and modern doctrines based upon the most recent work.

That *difficiles morbos* refers to malarial fevers may be well assumed, since they not only now form but have formed throughout historical times the most common and severe diseases of Italy. To the wide extension of these diseases bear witness the many recently-discovered drainage-systems, the object of which, as has been shown by Secchi, Tucci, and Tommasi-Crudeli, was to relieve the land of this scourge.

The *animalia* is a discrepancy less wide than it at first appears. It is not so long a time since the schizomycetes were regarded, on the authority of Ehrenberg and Dujardin, as animal organisms and classed as vibriones with the Infusoria. For the first time in 1853 were they recognized by Cohn as plant-forms, and referred to the Algæ; later Nägeli classified them with the Fungi as "spaltpilze."

Aside from this point of difference between the modern view and that of Varro, the description is marvellously accurate. The disease-exciting organisms are too small to be seen by the eye,—microscopic, as we say; they are in swampy places, where they develop under the favorable conditions of moisture and heat, and rather in the moist earth itself than in the water; from the surface of such earth, so soon as it is dried by summer heat, and thus exposed, they are wafted into the air; they gain access to the body chiefly by the organs of respiration; finally, they are the occasion of affections that may well be termed *difficiles morbos*. High temperature, splenic enlargement, with pigmentation of its substance, enormous development of malarial bacilli in the blood, spleen, and marrow, have followed the artificial infection of guinea-pigs by Klebs and Tommasi-Crudeli, a description that corresponds in all respects to the disease produced by natural infection in the human being, where the organisms *per aëra intus in corpus per os et nares perveniunt atque efficiunt difficiles morbos*. For Marchiafava found the malarial bacilli in the spleen and marrow of three cases of pernicious fever, and the same author—and, after him, Cuboni, Marchand, Rozaheggi, and Ziehl—found in the blood of ague-patients bacilli seemingly identical with those of Klebs.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THIS is the holiday season, and little is going on in medicine, beyond the necessary attention to the sick and dying, for Death wields his scythe irrespective of seasons and convenience. In many instances a difficulty has been experienced in finding a consultant in cases of emergency; and it seems to me that it would be no bad thing to have a list somewhere of who are in town and who are out, for such emergencies; only, where could it be kept? Then, again, whose names should appear, and, what is more, whose names should *not* appear? There are certain difficulties in the way of such an arrangement, but they are difficulties which could be got over if approached in a spirit of earnestness and honesty. Why should not a list be hung up at the Colleges of which public notice could be given, so that the practitioner in attendance upon any case could direct the messenger where to go in order to get the required information? This would not be advertising any one's name, because it would not be bringing names before the public, but only informing the public where to go to see who is in town at any particular time. If it were known that such lists existed and where they could be seen and consulted, much inconvenience could be avoided without injury or detriment to any one. Such a scheme is

practicable without any charge of advertising being brought against those whose names appear. Some heart-burnings there would be, doubtless; but it would not be impossible to draw a line. At the College of Surgeons it could be drawn at the Fellows, and at the College of Physicians at the Fellows and members. If a man is not in request on other accounts, the appearance of his name on the list would do neither him nor any one else good or harm. That something of this kind must be instituted ere long is as certain as that sickness does not strictly follow the season and avoid the holiday. It is very awkward for a general practitioner in attendance upon a grave case, perhaps a really important life, not to be able to find a consultant when a consultation becomes desirable. A friend of the patient is sent into town, and wanders about here and there till he finds some one to take out with him, perhaps some one who is far from what is desired, while, likely enough, a man possessed of the knowledge requisite to the proper understanding of the case is at home, only the messenger knew not where to find him, even if he knew of him at all. If such lists were kept at the Colleges, the practitioner could write up to the porter to ask if certain men were in town, and, if not, if certain other men were at hand. There could be no objection to such an arrangement, which would be of infinite service to the public, unless it were raised by some interested persons. A well-known consultant goes out of town and leaves directions that any patients who call shall be sent on to certain *protégés* of his, if necessary. But it is by no means a necessary sequence that his selection is also that of the patient, who very probably would prefer some one else. But to wander about London, calling first at one door and then at another in vain, seeking a consultant, is scarcely an attractive prospect for a person out of health. Nor is to write to ask several men if they are at home much better, when likely enough the letter will form one of a weekly batch sent off to North Wales or the Border. Men's names are known in connection with certain classes of maladies, and it would not be a practical difficulty for a general practitioner to ascertain which of them were available in an emergency where their counsel would be of service to him and his patient, if such lists were kept. The reader may possibly experience a difficulty about the line I draw at the College of Surgeons as compared to that at the College of Physicians, and, in order to make all plain to him, it may be well to explain the respective positions at the two Colleges. The membership of the College of Surgeons is the examination for entering the profession, corresponding to the licentiateship of the College of Physicians. The next step is an examination of a higher order, for the Fellowship of the College of Surgeons or the membership of the College of Physicians, and a good sound examination it is in each case. This examination passed, the surgeon takes his permanent position as a Fellow of his College, and is eligible for a hospital appointment. But with the physician he becomes only a member, which puts him on the list of consultants: there is a further step, and he may be promoted to be a Fellow of his College, on what terms no one seems to know, beyond that he must gain the support of eleven out of the fifteen electors, and how their choice is guided is a profound mystery. It is not inspired by heaven; that is pretty evident! What is requisite to gain a man the support of these eleven electors has never transpired or been made public. Out of these Fellows the lecturers before the College, the examiners, etc., are chosen, and to be merely a member is to stand out in the cold as regards the perquisites of the College. But the Fellows of the College of Physicians are a select body, albeit so mysteriously elected. A curious illustration of this is furnished by the post-office directory. In this the Fellows are indicated by a star (*), the members by a dagger (†), and the licentiates by a double dagger (‡), so that the public shall know beyond the possibility of doubt or cavil who are the men honored by the College. By what underhand proceedings, by what "ways that are dark and tricks that are vain," this classification was engineered, it is not possible to say. Whether the audacity or the impertinence of the classification is the more remarkable, transcends the judgment of ordinary minds. If it is desirable to draw such distinctions between the lower and higher divisions in the case of physicians, why, in the name of common sense, is it not extended to the surgeons? On the other hand, if surgeons are not to be marked off into higher and lower strata, the division-line being a very stiff examination, why should physicians of the higher class be marked off when the division-line is not a solid examination, but a shadowy semblance of a boundary, founded on nothing more substantial than caprice or favoritism? The utter absurdity of the thing as it at present stands is obvious to any one who takes the trouble to examine into the matter. It is pretty certain that the publishers of the Directory must have been induced by some Fellow of the College of Physicians to make the distinction; and possibly the tempter hoped by such action to give himself and his co-Fellows a boost in public opinion. The inconsistency of the whole thing is absurd, and the distinction is so ridiculous that the wonder is that the College of Physicians does not request the publishers to remove these *indicia*. It certainly would if it had any respect for itself. The incident is a funny illustration of what a dignified (?) corporate body can stoop to, on the one hand, and, on the other, a curious instance of how some man has planned a microscopic device to give

some men a lift at the expense of others. It cannot be a surprise to any one that the position of the medical profession here is not what it really ought to be, when it can so utterly forget its duty to itself and its self-respect. There are some very indifferent traditions in the profession, which, instead of being forgotten, as they should be, are still lived up to by those who ought to be ashamed of them.

To turn to another topic, of a different character, the necessity for a more thorough understanding of digestion, its disturbances, and the means to be adopted where the digestive system is very much impaired as to its functional activity, is borne in upon one by the lessons of daily practice. Not only in conditions of acute disease, where the digestion is almost annihilated, but in some very pronounced cases of more chronic character, the subject of feeding the patient is one of paramount importance. Milk is our sheet-anchor, doubtless, but, unfortunately, milk is distasteful to many persons, while it is apt in certain cases to curdle so firmly in the stomach that the curd never falls to pieces again until voided per anum, in consequence of which it is worthless as a food, while the firm curd is a source of irritation to the bowels, setting up diarrhœa, and in cases of enteric fever even endangering the patient's life, by the possibility of tearing the bowels at some spot weakened by ulceration. Not even where the precaution is taken of mixing it with an alkali, as Seltzer water, or Vichy, or Vals water, can this risk be entirely obviated. At the London Fever Hospital, in order to avoid too firm curdling, and the consequential dangers thereof, some farinaceous material is added to the milk, so that the curd will not be too firm for subsequent disintegration. What is often wanted is something which will sit easily upon the stomach (for if it do not it is soon rejected by vomiting) and at the same time require but a minimum of the digestive act. This last is of cardinal importance. Such a food should contain material readily convertible into grape-sugar, a certain proportion of albuminoids, and some fat. Milk, with baked flour, comes nearly to this standard. By the act of baking, starch is advanced on its way to grape-sugar. Crusts of bread, the well-baked outer portion of the loaf, soaked in hot water and mixed with milk, present a form of starch requiring little saliva to complete its conversion into grape-sugar. The different "baby-foods," too, present great advantages as food for those who are either pronouncedly dyspeptic or whose digestion is partly impaired by acute disease. Where fluid food alone can be taken, the contact with the salivary diastase is too brief to be of much service, and unless the starchy materials have had some previous acquaintance with diastase they will in all probability be voided per anum unchanged. Probably in acute disease little diastase is formed, whether salivary or pancreatic. Be that as it may, it is well to be upon the safe side, by giving as food farinaceous material which has already been acted upon by diastase. Such a food is malt-extract, under whatever name it is sold. A good malt-extract is a valuable food,—a costly food, doubtless, but a food of priceless value at times of emergency. We are accustomed to look at malt-extracts too purely from their diastatic point of view,—*i.e.*, as artificial digesters of starch by their free diastase. But they possess a value beyond that, which is scarcely sufficiently recognized. Even where the diastase has been to a large extent killed by careless preparation, there remain the albuminoids in soluble form, the phosphates in like form, and so much maltose or digested starch. Consequently, a malt-extract is a very valuable food, and, what is more, is a food which sits well upon the stomach in almost all instances. Indeed, in a very bad case, seen some months ago, the medical man in attendance upon the case had tried every food which the patient could tolerate, except malt-extract, and the only thing left for me to suggest was that a teaspoonful of malt-extract be given every hour. This was done, the stomach did not resent the presence of so small a bulk, and after a fortnight other food could be taken, and soon the patient got quite well.

In another case, a like quantity of the Cremor Hordeatus (Loefflund's Alpine Cream preserved with malt-extract) gave most desirable results. In fact, in very grave gastric cases malt-extract is a food which may often be resorted to when almost at one's wit's end what to do. This food can be taken either alone, or mixed with milk or with Seltzer water, as the patient pleases, and can either form part of a meal or be taken betwixt meals, or it can be added to beef-tea or chicken-broth. Such meat-tea alone has a very small food-value, but the addition of baked flour or malt-extract makes a mighty difference, and the combination constitutes a capital food. In cases of phthisis where the digestion is upset and there is a palpable danger of the patient sinking from inanition, such food is indicated, and is usually well borne. It may alternate with milk with advantage. It must be borne in mind that just as a variety of food is craved for by people in health, so some variety is relished by the dyspeptic. Milk, with Seltzer water, may precede some beef-tea with baked flour, and that again be followed by some compound food containing maltose, with milk. Murdock's Liquid Food is said to agree well with an irritable stomach, but I have no personal experience to offer on the subject. Then some stewed fruit may be given in such cases where it agrees with the patient. But cane-sugar is very apt to undergo acetous fermentation in the stomach, and so give rise to much acidity, and hence is contra-indicated in many cases.

But, where it can be taken, the juice of stewed fruit makes a pleasant change; though, unfortunately, this is not often the case. More frequently the changes must be rung on milk and malt-preparations. Maltose differs widely from cane-sugar in the liability of undergoing acetous fermentation in the stomach, rarely, if ever, undergoing that change. This is another argument in favor of malt-extracts for invalids. Indeed, there seems a great prospect before us, in a very troublesome class of cases, of being able to surmount the difficulty in feeding the patient by means of the skill of the chemist. Of course there is another matter to be attended to, which is not unimportant, and this is, that, as only a small bulk of food can be taken at once, it is necessary, in order to provide the patient with a sufficiency of nourishment, that these little meals should be taken at frequent intervals. About one-third of a pint, at once, every two hours, is enough to start with, and as the stomach gains power the quantity can be increased. But, as variety is pleasant to all, a little white fish boiled may be added to the "baby-foods" after a certain amount of improvement has been attained. It is as well, however, to remember the old proverb, "the more haste the less speed;" for never is the truth of the adage more forcibly illustrated than in the case of dyspepsia, where precipitancy and anxiety to get on very commonly defeat their own aim. A little bismuth with soda and nux vomica is a good combination, so far as medicines are concerned, to commence with. But ipecacuanha is the drug *par excellence* when it can be borne. That this is an hepatic stimulant of no mean power is now generally admitted. It is notorious that in full doses ipecacuanha is an emetic. In smaller doses it increases the activity of the gastric secretion while stimulating the muscular fibres of the stomach. Consequently, it is a drug of great potency in cases of deficient power in the digestive organs; and, as a pill, two-thirds of a grain of ipecacuanha, with a dose of strychnia, a little black pepper in extract of gentian, or aloes and myrrh pill, or compound colocynth pill, according to the state of the bowels, is in constant use with me in cases of indigestion. By it before meals, and McKesson & Robbins's egg-shaped pepsin pills after, the number being regulated by the patient's necessities, and a suitable regimen, ordinary cases of indigestion can be made to move on satisfactorily. But there is a lower stratum than this,—viz., a class of cases where only the most easily digested foods can be taken at all; where the stomach cannot be bullied, and where compromise alone is practicable. In these very troublesome cases "baby-foods" are our sheet-anchor to start with. And even when something approaching an ordinary meal can be taken in small quantities, a glass of milk with some good malt-extract in it—about two hours after the meal, when the contents of the stomach are passing the pyloric ring—is a good addition to it. The increasing failure of digestive power of the present day calls into action the skill of the chemist; and, fortunately for dyspeptics, the chemist possesses the skill.

J. Milner Fothergill.

PROCEEDINGS OF SOCIETIES.

LEHIGH VALLEY MEDICAL ASSOCIATION.

This flourishing young Society held its fourth annual session at Mauch Chunk on Tuesday, August 19. There were present of the Association, including those elected at this meeting, sixty members. Besides, there were some forty others, who, with wives and daughters, made the grand gathering number nearly two hundred.

The principal session was held in Concert Hall in the morning, and during this session the ladies were exploring the recesses of Glen Onoko.

The Association was called to order by its President, Dr. R. Leonard, of Mauch Chunk, who, after the roll-call, delivered the President's Address of Welcome. He selected as his topic "Some of the Obstacles and Difficulties in the Way of the Scientific Practice of Medicine: more especially in Country Practice." This address well merited the close attention it received: it was true to the life. He classified the difficulties under—1, a want of care in nursing; 2, ignorance of the really "professional" nurse (professional because they profess); 3, the general ignorance of the average man of his own physical make-up; and, 4, the worst foe,—those in our own ranks or who borrow our name for their own individual ends.

At the conclusion of the address, most of the business was transacted, and then the audience was delighted with Prof. Parvin's paper on the "Tampon." (See page 8.)

The only thing to mar the address was the approach of the dinner-hour, causing the lecturer to hasten. The heartiness with which the vote was given to thank Prof. Parvin for his address, and again to make him an honorary member of the Association, was an evidence of the appreciation of the Association.

After dinner, the Association and guests took cars for a trip around the Switchback. A short session was held at Summit Hill, to receive and act upon the report of the Nominating Committee.

Dr. Joseph Thomas, of Quakertown, was elected President, and Dr. Charles McIntire, of Easton, was re-elected Secretary.

The Carbon County Society furnished a refreshing collation, and the cars were taken back to Mauch Chunk, by gravity. A handshaking, good-byes, and embarking on the trains brought the session to an end. C. M.

REVIEWS AND BOOK NOTICES.

ATLAS OF FEMALE PELVIC ANATOMY. By D. BERRY HART, M.D., F.R.C.P.E., Lecturer on Midwifery, School of Medicine, Edinburgh, etc. New York, D. Appleton & Co., 1884. 4to, cloth.

This beautifully-printed atlas consists of thirty-seven full-page quarto plates and accompanying letter-press, not only illustrating the various elements constituting the female pelvic anatomy in a normal condition, with numerous dissections, but also showing various displacements caused by posture, pressure, or pregnancy. The illustrations are fine specimens of lithographic work in colors, except the microscopic reproductions, which are apparently by the heliotype process. There are also a number of wood-cuts given in an appendix in explanation of some points in the physics of the bladder and rectum.

Dr. Hart needs no introduction to American readers of gynæcological literature: it is, therefore, especially gratifying that this magnificent work was published in this country and under the direct supervision of Dr. Alexander J. C. Skene, of New York.

A study of these plates—many of which were original and are beautifully executed, every care having been exercised to obtain accurate representations from nature, others being from well-known monographs—will serve in a measure to correct some of the crude and imperfect knowledge of the relations of the pelvic viscera which has grown out of the errors of the popular text-books and led to confusion of ideas as to the pathology of many disorders of the organs involved, and no little discussion as to their diagnosis and proper treatment. We advise those interested in the diseases of women to examine this book for themselves.

THE THEORY AND PRACTICE OF MEDICINE. By FREDERICK T. ROBERTS, M.D., etc. With Illustrations. Fifth American Edition. Philadelphia, P. Blakiston, Son & Co., 1884. pp. 1008, 8vo.

Compared with the previous edition issued four years ago, the text of the present shows on nearly every page evidences of careful, intelligent revision. There is a full appreciation of, and due consideration given to, the many additions to modern pathology and therapeutics which have been made in that time. It is characterized by clearness of style, directness of expression, correctness as to its teachings, and brevity without dogmatism. The numerous additions, which would have otherwise materially increased the size of the work, have been provided for by a slight reduction in the size of the type; and the change from two volumes to one makes the work rather more acceptable to American readers, on account of the greater convenience for reference. The present edition fully maintains the standard of a work for the merits of which we entertain a high opinion as a most useful, correct, and practical work on the practice of medicine for the student either before or after graduation.

GLEANINGS FROM EXCHANGES.

THE NEOPLASTIC DIATHESIS.—M. Verneuil, in an address delivered before the International Medical Congress, said that he desired to prove: (1) that all true neoplasms, by the identity of their constitutional origin and their primary causes, make up a natural pathological group; (2) that they grow by virtue of a special disposition of a particular morbid disposition,—in a word, of a diathesis which he calls neoplastic; (3) that this diathesis is neither original nor independent, but derived from a much more general constitutional derangement,—arthritism. This led him to say that the true neoplasm is an arthritic manifestation of the same type with biliary gravel, eczema, rheumatism, gout, etc. He explained at length these three propositions, commencing by a general review of neoplasia and its varieties, as well as of the different neoplasms. Among these last he retained only those which he called idiopathic or true, and after setting forth their anatomical, physiological, clinical, and etiological characters, he arrived, by summarizing these characters, at the following definition. A true neoplasm is an accidental organ, definite, superfluous, and harmful, formed by the hyperplasia of anatomical elements and tissues morphologically and chemically altered,—an organ which is the seat of a perverted and disordered nutrition and a local manifestation of a particular diathesis, having its root in the arthritic dyscrasia. This definition has as its object the definite constitution of the group of neoplasms, too often confused with that of tumors. In the second part of his address, M. Verneuil drew attention to the fact that the etiology of neoplasms was imperfectly known and not sufficiently studied. He criticised the etiology at present accepted, and, in particular, the abuse which has been made of the word diathesis. He admitted but one diathesis for all neoplasms, at all ages, and in all conditions. This diathesis he believed to be hereditary. When it existed in a family, it could transmit itself to the descendants under a like or a different form. The oneness of the diathesis was proved, further, by the multiplicity and the diversity of the neoplasms in the same subject at one and the same time, or at different periods of life, by the multiplicity of pathological tissues in one and the same tumor, by the substitution of one form of neoplasm by another at the same spot. He examined, with the view of refuting them, the objections to the oneness of the diathesis,

based on the differences of structure, of the course, and the gravity of the different neoplasms. He further laid it down that, if the ordinary causes cannot give rise to a neoplasm without the neoplastic diathesis, this in turn is powerless to produce anything of itself, and without the aid of the requisite causes. In the third part of his address, M. Verneuil, recognizing that the admission of a diathesis does not determine the question of etiology, set himself to prove that the neoplastic diathesis springs directly from arthritism, an idea already introduced to science by Bazin, but so far imperfectly demonstrated. He brought in as arguments supporting it the association, or the almost constant association, of neoplasms and arthritic manifestations, and, at the same time, the extreme rarity and almost incompatibility of these same neoplasms with scrofula, itself far removed from arthritism. Professor Verneuil, in concluding, said he did not conceal from himself the fact that his ideas presented a broad side to criticism, and that he must, to have them accepted, keep up facts and proofs. He had not, however, hesitated in laying them before the Congress, in the hope that they would give rise to both discussion and observation, and would contribute, by the study of etiology, to raise practice out of the pure surgical path, in which at present it was exclusively occupied.—*British Medical Journal.*

The Etiology of Tuberculosis.—With a view to prove the exact relationship of tubercle to the bacilli with which it is associated, further investigations have lately been carried on by Koch, and he lays down the following statements:

The bacilli are always found in greatest abundance in those tissues where the tuberculous process is most active, whilst, when the caseous masses appear, the bacilli disappear, and assume a spore-like condition, in which they cannot easily be stained, and are therefore easily overlooked. In all the slower tuberculous processes, *e.g.*, those which are observed in joints, the bacilli are only found in the giant cells, and often one bacillus only is present in each giant cell. These giant cells are produced from simple cells by the irritation of the bacillus. If the process is a very rapid one, it does not end in caseation, but in the shrivelling up of the cell, and injection of the neighboring connective tissues.

In scrofulous lymphatic glands, and in joint and bone affections, if the bacilli are found at all they are very rare. This is also the case with lupoid affections. In some cases forty or fifty sections will reveal only one bacillus.

When these various tuberculous deposits were employed for injection purposes the same result was produced in animals of the same species and variety. Even the slightest variety in an animal gave a variety in the result: *e.g.*, whilst the field-mouse was very susceptible to inoculation, the white mouse was not.

Sometimes the same animal at different times showed a varying susceptibility; and this result Koch is inclined to ascribe not so much to variety in the infective material as to the resisting power of the individual. (*Mittheil. aus dem kaiserl. Gesundheitsamte*, vol. ii., Berlin, 1884.)—*Practitioner.*

The Color of Cannabis Indica.—It having been asserted by Dr. Maclagan that the green color of the extract of cannabis indica is due solely to the presence of copper, Dr. Squibb has made a series of experiments which prove that it is due originally to chlorophyll, and that a fluid extract could be made without a trace of copper, although a trace could be detected in commercial specimens in the proportion of 1 to 3700 parts, therefore in a quantity too small to do harm. In future this accidental impurity will be avoided by Dr. Squibb by the substitution of glass for copper vessels in making the extract.

Cholera-Germs.—Drs. Maurin and Lange, who have been working at Marseilles since the departure of Koch, claim that they have discovered the missing link in the propagation of the cholera-bacillus, in the shape of a mucor which appears on the fourth or fifth day on putrefying cholera-stools, and on these only. It has the form of a mycelium with cup-shaped sporangia, which burst on the slightest agitation, discharging vast quantities of spores, which, after deposit upon putrid organic matter, develop into an anaerobium, which they believe to be the immediate cause of cholera, and which in turn sporifying produces the bacilli of Koch.—*British Medical Journal*, September 6.

Sulphocarbolate of Zinc, says the *Riv. Ital. di Terap.*, is a valuable disinfecting material, whose good qualities, though long known, have been passed over in favor of less active agents. Bottini has recently been experimenting with it, and warmly recommends its use in antiseptic surgery. A five-per-cent. solution is quite strong enough, and it may be used in the form of spray or applied by compresses, etc. It is also useful for the disinfection of knives and other instruments.—*National Druggist.*

MISCELLANY.

An English Cholera Commission.—The English government having directed Dr. Klein and Dr. Heneage Gibbes to go to India to pursue a scientific inquiry into the nature of cholera, they have sailed for the scene of their labor. It is understood that these gentlemen will act in conjunction with the commission nominated a few weeks ago by

the Indian government for the same object.

A WARNING TO BATHERS IN THE SCHUYLKILL.—A boy who was recently bathing in the river Medlock, in Manchester, got out of his depth and swallowed some of the water, which was particularly filthy. Though immediately rescued by another lad, he expired shortly afterwards, death, it is stated, resulting not from drowning, but from poisoning.—*Lancet.*

A MEDICAL COLLEGE SUED.—Suit has been entered against the Georgia Eclectic Medical College of this city for fifteen thousand dollars. It is alleged that the Faculty violated the State law by graduating students who had not attended two full courses of lectures.—*Atlanta Medical and Surgical Journal.*

WE learn from the daily press that some friends of Dr. J. V. Shoemaker, of this city, gave him a dinner at the St George Hotel on Saturday night, the 20th of September, to welcome him on his return from Europe.

THE AMERICAN PUBLIC HEALTH ASSOCIATION holds its annual session this month, in St. Louis, Missouri, commencing on the 14th and ending on the 17th, at which A. L. Gihon, M.D., U.S.N., will preside. A large and interesting meeting is expected.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE held a very successful session in this city last month, which was honored by the presence of a large number of visitors from the British Association. The official report of the proceedings of the meeting will appear in *Science.*

JUDGE ELCOCK recently decided that the Act of Assembly with regard to the sale of poisons does not apply to physicians' prescriptions, and the clerk of Mr. McKelway was very properly discharged from custody for not labelling a box of pills "Poison," although, being taken in excess of the amount directed to be administered, they caused the death of a young girl.

DRS. PROTHERO AND HEYWOOD SMITH, distinguished gynæcologists of London, father and son, who have been visiting the city, were entertained at lunch by Dr. Albert H. Smith on the 20th ult., and met a number of invited guests.

NOTES AND QUERIES.

WOMEN STUDENTS IN VIENNA.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—It seems very true of each one of us that, as we go through the world, we find that which we seek, and fail to see that which does not interest us.

Being a woman, and having spent a year in study at Vienna, I would like to supplement the "Letter from Vienna" contained in your number of July 26 by giving you a short sketch of the medical work women are enabled to do in the "Allgemeines Krankenhaus."

The chief attraction for foreign students is the series of private classes for diagnosis and practical work in the hospital wards, taught by the assistants and docents. To these classes only those can be admitted of whom the professor of the department approves. It is necessary for a woman coming to Vienna for study to be able to show a diploma of graduation from a recognized medical school at home, and, as a rule, to meet the professor of the department personally. With his approval, she then enters the same classes with the men.

During the past year twelve women (English and American physicians) have taken courses in the hospital: four Englishwomen, one a graduate of the London University and three from the King's and Queen's College of Physicians in Ireland. The remainder were Americans, and graduates of the medical schools in Boston, Philadelphia, Chicago, and San Francisco.

Two American women who are at present in Vienna are recent graduates of the Paris "École de Médecine," which admits women as matriculates and enables them to take the same courses, pass the same examinations, and confers upon them the same diplomas men receive. A Roumanian lady, a graduate of this school, has also recently gone to Vienna for study.

The professors and assistants whom we have met during the past year have treated us most courteously, and we have enjoyed privileges for study in the same classes with the men in the clinics, wards, and laboratories of Professors Billroth, Kundrat, Kaposi, Nothnagel, Schrötter, Stellwag, Wiederhofer, Bamberger, Politzer, Salzer, and Exner.

Three large sections of the hospital, belonging respectively to Professors Carl Braun, Gustav Braun, and Späth, consist of the lying-in wards. These are open in turn, each for twenty-four hours, for the reception of women in labor. Ten thousand births take place here every year.

Prof. Gustav Braun has the department for the training of the midwives under his charge. (Prof. Späth has not been connected with this branch of the work for at least ten years.)

Professors Carl Braun and Späth do not admit women-physicians to their lying-in wards, although Prof. Späth gave his own card to one of our ladies, introducing her to his assistant, Dr. Lumpey, with whom she desired to obtain work in gynæcology.

Women-physicians enjoy greater facilities for obstetrical work than they could obtain in the wards of either of the above professors, by taking the private courses in the wards belonging to Professor Gustav Braun, which do not admit men. These consist in a "touch course" (the examination of pregnant women), an operative course on the phantom, and a series of obstetrical operations, versions, breech deliveries, forceps deliveries, etc., on the living in the lying-in wards. The midwives take charge of normal labors alone, and have special lectures and demonstrations from Prof. Gustav Braun. Any woman-physician desiring to study the phases of labor in a number of cases, and willing to enter upon the drudgery it entails, has the privilege of entering the school for midwives. This does not exclude her, however, from the physician's course. One of our number, desiring to give special attention to the subject, took both courses at the same time during the past year.

I am surprised that Dr. Wilson's memory should have failed him on these points, as I know he must have learned them from the four women-physicians who boarded at the same *pension* with himself in Vienna.

In a letter which I had occasion to write Dr. Wilson during his short stay in Vienna, I spoke of our inability to enter certain courses at the time. I had reference then to courses in gynæcology, most particularly a touch and operative course given by Dr. Pawlik, docent in Prof. Bamberger's clinic. Since Dr. Wilson left Vienna, this course has also been opened to women, a lady from Winchester, Massachusetts, having taken it during June and July. I myself had the privilege of visiting his clinic, and the promise of a place in his next class (he admits only four at a time) could I wait until October. Two American women have their names already put down by him for that course.

Dr. Lott, also a privat-docent of the university, has given four women an operative course in gynæcology during this summer: so that I know of no branch of the work now in which women do not enjoy equal advantages with the men.

Dr. Wilson will pardon me for making this correction, as I felt in part responsible for his misunderstanding. In one of his letters to me he states that he considers the movement for the medical education of women as requiring "active measures for suppression." This feeling has, I fear, led him to do us this injustice in not presenting the true facts of the case. Had he said we could not matriculate in the Vienna University and take the lectures with the students and the university examinations, he would have been correct (an institution which does not offer a medical education to the women of its own country cannot be expected to do that for

foreigners); but to say that we "have failed to gain any recognition in Vienna" is a grave error, to which not only the women studying there, but the professors and assistants, can testify.

ANNA M. FULLERTON.

PARIS, August 23, 1884.

[From a letter of Dr. Carl Breus, privat-docent in the University of Vienna, and recently assistant to Prof. Gustav Braun, written August 28, 1884, we take the following upon the same topic, confirming Dr. Fullerton's statements.—ED. MED. TIMES.]

"Dr. Anna M. Fullerton has recently shown me a letter from Vienna in the *Philadelphia Medical Times* of July 26 of this year, and requested me to write to you.

"What is said in said journal about the position of women-physicians with the faculty of Vienna is in point of fact incorrect. The *legal matriculation* of women for medical study in Vienna, it is true, is not permitted; but most of the professors afford to women-physicians from abroad an entrance to the institutions which they teach *as guests*, precisely as they do to the men-physicians.

"The courses of most of the assistants and docents stand open for women, and are resorted to by them. I myself have repeatedly taught operative obstetrics in courses for women-physicians as assistant in the clinic of Prof. Gustav Braun, covering all the ground proper for the instruction of physicians, and not merely such as would be given for midwives. On the whole, the women-physicians who visit the clinic of Prof. Gustav Braun have there the full rights of doctors, and stand entirely apart from the midwives, who are separately taught.

"They are allowed, under my supervision, to perform for themselves the difficult operations on women in labor, which are in no case whatever permitted to the midwives, who are never allowed to make even an episiotomy.

"At the clinic of Profs. Carl Braun and Späth women-physicians are not admitted; but at the clinic of Prof. Gustav Braun women have the opportunity of acquiring all practical and theoretical obstetrics. For these facilities they are to be envied on account of the less abundant amount of material divided among the frequenters of both the other clinics."

[These communications were shown to Dr. Wilson, who writes as follows:]

MR. EDITOR:

DEAR SIR,—In reply to the above, I would simply state that I disclaim any intention whatever either to suppress or exaggerate the facts: I merely presented them to your readers as they appeared to me while recently in Vienna.

Truly yours,

CHARLES MEIGS WILSON, M.D.

1517 WALNUT STREET, PHILADELPHIA.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM SEPTEMBER 14, 1884, *TO SEPTEMBER* 27, 1884.

CALDWELL, D. G., MAJOR AND SURGEON.—Granted leave of absence for one month and twenty days, to commence about October 15, 1884. S. O. 95, Headquarters Division of the Missouri, August 16, 1884.

MIDDLETON, PASSMORE, MAJOR AND SURGEON.—Having reported from sick leave of absence, assigned to duty at Fort Leavenworth, Kansas. Paragraph 2, S. O. 188, Headquarters Department of the Missouri, September 19, 1884.

CRONKHITE, HENRY M., CAPTAIN AND ASSISTANT-SURGEON.—From Department of the Platte to Department of the Missouri.

TAYLOR, ARTHUR W., LIEUTENANT AND ASSISTANT-SURGEON.—From Department of the Missouri to Department of the Platte. Paragraph 1, S. O. 215, A. G. O., September 13, 1884.

WHITE, R. H., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty as post-surgeon at Fort Winfield Scott, California, relieving Assistant-Surgeon A. S. Polhemus, who, upon being relieved, will report to the commanding officer, Alcatraz Island, California, for duty. Paragraph 1, S. O. 113, Headquarters Department of California, September 19, 1884.

HALL, JOHN D., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty at Fort Townsend, Washington Territory, to relieve Surgeon R. S. Vickery.

Surgeon Vickery, on being relieved, directed to report to commanding officer, Vancouver Barracks, Washington Territory, for duty. Paragraph 3, S. O. 140, Headquarters Department of Colorado, September 15, 1884.

WILSON, WILLIAM J., CAPTAIN AND ASSISTANT-SURGEON. From Department of Dakota to Department of the East.

GARDINER, J. DE B. W., CAPTAIN AND ASSISTANT-SURGEON.—From Department of Arizona to Department of the East.

CORBUSIER, WILLIAM H., CAPTAIN AND ASSISTANT-SURGEON.—From Department of the East to Department of Arizona.

LA GARDE, L. A., CAPTAIN AND ASSISTANT-SURGEON.—From Department of Missouri to Department of Dakota. Paragraph 1, S. O. 220, A. G. O., September 19, 1884.

TESSON, L. S., CAPTAIN AND ASSISTANT-SURGEON.—Directed to report to commanding officer, Fort Stockton, Texas, for temporary duty. Paragraph 3, S. O. 127, Headquarters Department of Texas, September 22, 1884.

BIRMINGHAM, H. P., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Leave of absence extended twenty days. Paragraph 2, S. O. 116, Headquarters Division of the Missouri, September 22, 1884.

MADDOX, T. J. C., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Directed to report to commanding officer, post of San Antonio, Texas, for duty. Paragraph 5, S. O. 127, Headquarters Department of Texas, September 22, 1884.

BARROWS, C. C., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Granted one month's leave of absence, with permission to apply to the proper authority for an extension of one month. Paragraph 4, S. O. 86, Headquarters Department of Arizona, September 13, 1884.

BARROWS, C. C., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Leave of absence extended one month. Paragraph 6, S. O. 97, Headquarters Division of the Pacific, September 19, 1884.

DIETZ, W. D., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Assigned to duty at Fort Selden, New Mexico, (post-surgeon). Paragraph 4, S. O. 187, Headquarters Department of Missouri, September 18, 1884.

MCCAW, W. D., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Assigned to duty as post-surgeon, Fort Craig, New Mexico. Paragraph 5, S. O. 187, Headquarters Department of Missouri, September 18, 1884.

LIST OF CHANGES OF STATIONS OF NAVAL MEDICAL OFFICERS FROM SEPTEMBER 14, 1884, *TO SEPTEMBER* 27, 1884.

P. A. Surgeon G. E. H. HARMON, September 16, from Navy-Yard, Norfolk, to Naval Academy.

P. A. Surgeon W. A. MCCLURG, September 16, from Naval Academy to Naval Hospital, Philadelphia, Pa.

P. A. Surgeon PHILIP LEACH, September 16, from Hospital, Chelsea, Mass., to the "Palos."

Surgeon J. W. COLES, September 16, as member and recorder of Naval Examining Board, and to Hospital, Philadelphia.

P. A. Surgeon E. Z. DERR, September 16, to Navy-Yard, New York.

Surgeon B. S. MACKIE, September 16, from Training-Ship "Jamestown," as member and recorder of Naval Examining Board.

Medical Inspector D. KINDLEBERGER, September 18, from "Hartford," sick.

P. A. Surgeon S. H. DICKSON, September 19, permission to leave United States.

Medical Inspector D. BLOODGOOD, to Washington, for examination preliminary to promotion and as to qualifications for sea-duty, October 1, 1884.

Medical Director W. T. HORD, as member of Naval Examining Board, October 1, 1884.

Medical Director T. J. TURNER, as member of Naval Examining Board, October 1, 1884.

P. A. Surgeon J. C. BOYD, placed on waiting orders, September 25, 1884.

Surgeon A. S. OBERLY, to Washington, for examination preliminary to promotion and as to qualifications for sea-duty, October 1, 1884.

PHILADELPHIA, OCTOBER 18, 1884.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE CLASSIFICATION OF LARYNGEAL NEUROSES.

A Summary from Demonstrations at the New York Polyclinic.

BY LOUIS ELSBERG, M.D.,

Professor of Laryngology and Rhinology.

GENTLEMEN,—To-day I am going to redeem my promise to give you a connected account of my classification of laryngeal neuroses. This classification is one for practical purposes, and is partly physiological and partly anatomical, to facilitate analysis and understanding of the morbid conditions as they present themselves. As you know, laryngeal neuroses concern either sensation or motion, or both sensation and motion combined. During the session about to close we have had before us a number of patients illustrating the various affections to which the designation "laryngeal neuroses" is properly applied. We have excluded from that category every case in which the disorder was not what is called "functional;" *i.e.*, every case in which morbid sensation depended upon inflammatory or other structural change of the part, or in which motion was interfered with by organic or mechanical causes. With this restriction, you have seen that laryngeal disordered mobility is much more frequently met with than disordered sensibility, and that while the latter, except in certain general conditions of the system, very rarely occurs without (at least some degree of) the former, motor power over the vocal organs is often affected without interfering with normal sensation. To such motor disturbances I have given the systematic name "Laryngeal Dyskinesia;" to sensory, that of "Laryngeal Dysæsthesia."

I classify dysæsthesia (*a*) in reference to quantity or degree of sensation, as—I. Diminished sensibility, or hypæsthesia, and II. Increased sensibility, or hyperæsthesia; and (*b*) in reference to quality or kind of sensation, as—III. Perverted sensibility, or paræsthesia.

I have abundantly demonstrated to you that we must discriminate between three different kinds of sensibility of the throat,—viz., 1, tactile, by which temperature and pressure are appreciated; 2, dolorous, by which pain is appreciated; and 3, reflex, from which result muscular contractions, as well as intravascular and secretory phenomena.

The following tabular statement comprises the classification to which I have adhered for some years, and which I find most useful for designating the affection from which patients suffer. In individual cases some of the various conditions in the list are sometimes curiously combined, or exist on opposite sides of the larynx.

I. Hypæsthesia.	1. Anæsthesia.			
	2. Analgesia (Analgia, Anodynia).			
	3. Anæsthesia dolorosa.			
	4. Tactile hypæsthesia and hypalgia.			
	5. Reflex hypæsthesia.			
II. Hyperæsthesia.	1. Tactile hyperæsthesia.			
	2. Hyperalgia (algesia, hyperalgesia).	Spontaneous.		
		From external impression.	Peripheral.	Constant.
			In nerve-trunk, or neuralgia.	Paroxysmal, or true neuralgia.
	3. Reflex hyperæsthesia.	Muscular effects.	Cough, choking, spasm, etc.	
		Circulatory effects.	Flushing, paling.	
		Secretory effects.		
III. Paræsthesia.	The perversions of sensibility are so various that it is impossible to classify them or to enumerate them all. There are, however, perversions of tactile, of dolorous, and of reflex sensibility. Among the first mentioned, the most frequent are the sensation of heat or burning (the opposite—a sense of coldness—is very rare, but I have also seen that) and the sensation of the touch of a foreign body, attention being given mainly to its shape and its weight or pressure. Patients describe all possible and impossible shapes and materials in endeavoring to give an account of the perverted sensations. I have sometimes thought most of them might be arranged under the three heads,—1, sphæræsthesia; 2, zonæsthesia, or strangalæsthesia; and 3, akanthæsthesia; comprising, under the first, the sensation of a bulky body, generally ball-shaped; under the second, a cincture or band feeling, a sense of constriction; and under the third, the sensation of a sharp-pointed body, piercing or cutting.			

For a long time I thought that just as the cases of sensory disturbance, or dysæsthesia, are classifiable under the three heads of diminished, increased, and perverted sensation,—*i.e.*, hypæsthesia, hyperæsthesia, and paræsthesia,—so the cases of motor disturbance, or dyskinesia, might be classified under the three heads of di-

minished, increased, and perverted motion; *i.e.*, hypokinesia, hyperkinesia, and parakinesia. Such a classification has been adopted by Mandl, and I formerly followed the same. But more experience has convinced me that while the cases of laryngeal hypokinesia constitute paresis and paralysis (designating for convenience by the latter term entire loss of motion, and by the former incomplete loss, but comprehending both conditions under the general term paralysis), the cases of laryngeal hyperkinesia and parakinesia cannot properly be clinically separated, or rather that morbidly increased motion in the larynx is perverted motion; *i.e.*, that all the conditions of disordered mobility not of the nature of "paralysis" can properly be classed under the head of "spasm."

I. *Paralysis.*—This may be confined to a single muscle, or may implicate several muscles, or one or more sets of muscles. It may be in the domain of either the superior or the inferior laryngeal nerve, or may involve both, and come from disease or injury of either the pneumogastric or spinal accessory nerve, or the brain: in either case it may be bilateral or unilateral, and either partial or complete. In affections of the brain the paralysis is usually not limited to the larynx, but is associated with paralysis of the pharynx, palate, tongue, etc., as in progressive bulbar paralysis, locomotor ataxy, and general paralysis. We have more than once in this Polyclinic had the opportunity to observe the very curious fact that if in injury or disease of either the brain, or the pneumogastric, spinal accessory, or recurrent nerves, laryngeal paralysis is or becomes incomplete, the abductor filaments are more prone to be affected than the adductor filaments, and that if, in a case in which both the abductors and the adductors are affected, recovery takes place, the adductors are apt to recover first or exclusively, and to be affected with abnormal contraction, so that the patient during the progress of recovery is in danger of a dyspnœa, which may necessitate tracheotomy to prevent death. The relatively greater disposition to implication of the abductor filaments has been impressed upon the profession by Dr. Felix Semon, of London.

Paralysis in the domain of the superior laryngeal nerve involves, aside from anæsthesia, loss of power of the thyro-cricoid and the thyro- (and ary-) epiglottic muscles, while paralysis in the domain of the inferior laryngeal nerve implies either adductor or abductor paralysis, or both combined. A few years ago, I pointed out as a difference between the position of the vocal bands to which we may justly apply the term *cadaveric* (uninfluenced by muscular action) and the position which results when all the muscles except those innervated by the superior laryngeal nerves are paralyzed, that in the latter case the edges of the bands are slightly concave, while in the dead body, where the real cadaveric position is seen, and in paralysis involving the thyro-cricoid, thyro-arytenoid, arytenoid, and lateral crico-arytenoid, either with or without the posterior crico-arytenoid muscles, these edges are straight or even somewhat convex. I should much like to have other observers pay attention to this point, as it as yet lacks confirmation.

In the domain of the inferior laryngeal nerve, the adductor paralysis, causing phonatory leakage, involves, either singly or combinedly, paralysis of the arytenoid, thyro-arytenoid, and lateral crico-arytenoid; while the abductor paralysis, causing respiratory insufficiency, involves paralysis of the posterior crico-arytenoid. Paralysis of the lateral crico-arytenoid muscles is very rarely isolated; usually there is combined with it paralysis of either the arytenoid or the thyro-arytenoid, or both; sometimes the two latter are affected and the former are intact, or either of the latter may be affected alone. Paralysis of the posterior crico-arytenoid muscle occurs either alone or in combination with the adductors.

II. *Spasm.*—Paralysis of laryngeal muscles sometimes is followed by, or alternates with, spasm of the same or other muscles, and sometimes it seems to cause, or at all events is accompanied by, spasm of antagonistic muscles. Sometimes spasm is a reflex effect, and sometimes it is called forth by the very action of the muscles. It is either more or less *clonic* or more or less *tonic*, in the former the muscular fibres contracting and relaxing alternately in quick succession, in the latter the contractions remaining for a comparatively long time. It may be unilateral, but usually is bilateral, and is either simple or complicated with spasm of other muscles. It may affect either the abductors or, what is more usual, the adductors, and in this case

may either involve all or be limited to one or two of the adductor muscles. Hack has pointed out that isolated spasm of the lateral crico arytenoid muscles is more dangerous to life than spasm of all the adductors combined; and I have met with cases which entirely confirm Hack's experience.

For many years I grouped cases of laryngeal spasm according to a modification of Gerhardt's classification. This thorough clinician made the following four groups:

1. Those caused by direct irritation of laryngeal nerves.

2. Reflex laryngeal spasms, mostly arising from excitation of the superior laryngeal nerve, as when the mucous membrane, especially the lower face of the vocal bands, is touched, when foreign bodies are present in the air-passages, etc.

3. Hysterical laryngeal spasms, which are also reflex, and sometimes combine with spasm of the inspiratory and expiratory muscles.

4. Functional laryngeal spasms, analogous to writer's cramp, shoemaker's cramp, etc.

As my observations accumulated, I found Gerhardt's classification, and successive modifications thereof, inadequate. I had to enlarge especially the frame of functional spasms; under this designation Gerhardt had recorded two very interesting cases of "neurosis of occupation." In describing his second case, Gerhardt says, "This was evidently a case of spasm of an organ abnormally exercised, occurring at every attempt at over-exertion." I found cases in which laryngeal adductor spasm was evoked not only by the exercise of the function of phonation, but also by that of the functions of respiration and deglutition; and while in some cases over-exertion was necessary to bring on the attack, in others the quietest and most unexcited functional action of the larynx produced it. I therefore came to arrange these cases under the heads of deglutitory, inspiratory, and expiratory (including phonatory) adductor spasm. In addition to the simple forms of these four, special mention must be made of the complicated inspiratory and expiratory forms of adductor spasm; the former is that ordinarily known as laryngismus stridulus, the latter occasions very curious coughs. These coughs have been subdivided (*a*) as to their mode into the two kinds, paroxysmal and continuing, and (*b*) as to their acoustic quality, which is often very peculiar, as barking, quacking, crowing, lowing, etc.

In abductor spasm there is insufficient closure of the rima glottidis, and of course no possibility of making a laryngeal sound.

NOTE.—Since delivering the foregoing lecture, I have presented the subject of laryngeal spasm to the American Laryngological Association; and a reviewer in the *Internationales Centralblatt für Laryngologie, Rhinologie und verwandte Wissenschaften*, criticising my classification from a report published unofficially and without my knowledge in the *Philadelphia Medical News*, regards it as very artificial, and based more upon theoretical considerations than upon observations at the sick-bed: "stark gekünstelt und mehr auf theoretischen Erörterungen, als auf Beobachtungen am Krankenbett beruhend."

It is to be hoped that with more experience this evidently young reviewer will learn better. Before concluding his review he gives evidence, also, of carelessness, not to use a harsher word,—viz.: any one with understanding of the subject, or even without understanding, with attention to the context, would have known that the phrase "*spasm of all the abductor laryngeal muscles*" is a reporter's or a typographical error, especially as that phrase occurs in speaking of a variety of adductor spasm; but, according to this reviewer, the phrase *must be interpreted as showing a mistake in regard to the number of abductors of the vocal bands proceeding from false anatomical notions!*

The esteemed editor of the *Internationales Centralblatt*, if he wants to maintain a high standard for his periodical, must be more careful in the selection of his reviewer.

ORIGINAL COMMUNICATIONS.

REPORT ON THE PROGRESS OF OTOLOGY.

BY CHARLES H. BURNETT, M.D.,
Philadelphia.

HÆMATOMA AURIS.

UNDER this title, Dr. Samuel Sexton (*N. Y. Med. Record*, July 5, August 2, 9, and 16, 1884) has written the most elaborate essay on othæmatoma in the English language. In the author's opinion, othæmatoma, or sanguineous tumor of the auricle, may be produced either by severe contusion of the auricle, or it may, as is asserted, take its origin from idiopathic causes alone. Most frequently, however, the author thinks that it is due to violence, even where a predisposition to its occurrence exists. The size of the tumor varies from that of a Lima bean to that of an egg. Its formation is usually rapid, and the sanguineous contents of the tumor, at first fluid, show a marked tendency to become clotted, and quite often, unless incised, spontaneous rupture takes place. The disease most frequently occurs in the insane. The etiology of othæmatoma in the insane has long been the subject of discussion. Bird (1834) was at a loss to account for it, and Franz Fischer (1848) concluded that the causes must ultimately be sought for in pathological states of the nervous system. Dr. Sex-

ton believes that the intense congestion of the ears sometimes witnessed in connection with great cerebral excitement in the insane cannot but suggest the possibility of spontaneous extravasation of blood beneath the perichondrium. It is also held to be probable that certain tissue-changes in the perichondrium and cartilage may induce othæmatoma. These tissue-changes seem to be mainly brought about through the agency of the nervous system, although many authorities lay much stress on the influence of blood-dyscrasias in producing changes in the blood-vessels of the auricle. The author, however, holds that the "weight of evidence leads to the conclusion that they most frequently depend on a morbid state of the brain, especially on congestion of the organ." He also advances Robertson's idea that functional disturbance of the brain, or of its cerebro-spinal system, giving rise to disorder of the cervical sympathetic, may, by reason of the dominance thus exercised on the vessel-regulating nerves distributed to both intracranial ganglia and the auricle, set up hyperæmia in the former and vascular changes in the latter.

When othæmatoma occurs in the course of general paralysis, it would seem that auricular congestion took place in consequence of the general degeneration of the sympathetic; and it has been suggested by Bonnet that in inflammation of the brain the aural disease becomes advantageous to the patient, since the hemorrhage is thus spent upon the posterior auriculars, coming from the middle meningeal artery. "Other impressions propagated by morbid processes in other organs through the sympathetic nervous system are worthy of consideration: thus, in the examination of insane subjects having this affection, the almost universal prevalence of nasal catarrhs, diseased teeth, and (in the female) of uterine disease is notable, and it is well known that the irritation due to these influences is transmitted through the nerves, and may not only exasperate cerebral disease itself, but is liable to also affect the organ of hearing." The predisponents believed to have an important relation to othæmatoma are as follows: age (as it does not occur before adolescence), insanity, intemperance, cachexia, sex (the male being more liable than the female), and traumatic influences.

All forms of mental disease seem to be predisposing, but the conditions most favorable to othæmatoma are present in acute dementia where long-standing vaso-motor disturbances are followed by paroxysms of excitement.

Women are said to enjoy considerable immunity from the general paralysis of the insane, and consequently to escape the frequent paroxysms of excitement which characterize this phase of mental disease. On the other hand, women are subject to a monthly aggravation of symptoms during the menstrual period, since the mentally sane, even, are more irascible and nervous at this time. The treatment of female lunatics, moreover, is more gentle than that of males, since their attendants are usually of their own sex, and less liable than male nurses to injure in handling violent or idiotic patients. The ears of female lunatics are somewhat protected by their hair and head-dressings.

In the mentally sane, the affection is most commonly met with among prize-fighters, gymnasts, persons given to violent sports, and among drunken and disorderly persons, where blows and falls are frequent. "From a careful study of the subject, the author has come to believe that othæmatoma is almost always due to violence inflicted upon the auricle. Asylum superintendents, however, have been, on the whole, perhaps rather disposed to undervalue the importance of mechanical causes, since it might be construed to imply undue restraint or rudeness in the management of their patients. It is highly probable that violent patients injure their own ears in various ways, and even those who are not violent, but suffering from hallucinations of hearing, undoubtedly injure their auricles by picking at and pulling them in order to gain relief from subjective sounds, pruritus, etc."

The more frequent occurrence of othæmatoma in the left auricle of the insane has been the subject of much speculation. It has been suggested that the near position of the left carotid artery to the heart affords a more direct supply of blood to the left ear, and that, furthermore, the left pinna is more likely to be pulled by others, as it is most convenient to the right hand of the attacking party. It is also supposed that the left auricle is more likely to be pressed in forcible feeding. Dr. Sexton, however, thinks an explanation of the greater frequency of left-sided othæma-

toma must be sought in some other direction, since the above apply only to mechanical agencies. It has occurred to him "that probably some vaso-motor influence might be found to lie at the bottom of the difficulty." It is a fact that unilateral sweating about the head is not an uncommon occurrence, also the left ear is more rapidly invaded in bilateral chronic catarrh,—a condition, Dr. Sexton thinks, due in all probability to some vaso-motor disturbance whereby the nutritive process is interfered with much more on the left side than on the right side. While the agency may be found to lie in some cerebral or cerebro spinal condition, there exists a prominent irregularity in the distribution of the sympathetic nerves which, it occurs to the author, might bring about such a result. Reference is made in this connection to the peculiar arrangement of the nerves extending upward from the cardiac plexus to the two sides of the head. There is here an important irregularity. Thus, while an unvarying connection is maintained with the right side through the superior cervical ganglion, a comparatively imperfect and varying connection exists on the *left* side, the left superior cardiac nerve and the inferior cardiac branch of the pneumogastric only occasionally affording communication between the cardiac plexus and the left superior cervical ganglion. It is held that this asymmetrical distribution above described might be the means of diminishing the vaso-motor dominance in respect to the circulation in the left ear, and thus lead, by disparity of vascularity in the two ears, to distinguishing nutritive changes in the tissue of the two ears, changes which are well marked in chronic catarrhal otitis media, in which the left membrana tympani is frequently found parchment-like while the right membrane is normal, and which are also seen, as the author believes, in the nutritive disturbances in the cartilage of the left auricle in othæmatoma. Othæmatoma does occur simultaneously in both auricles, which form of invasion is "suggestive of centric nervous origin."

No distinction is made between othæmatoma and the so-called "idiopathic" perichondritis of the auricle, since in all cases of othæmatoma, perichondritis is never absent. A peculiar form of othæmatoma is mentioned as occurring in the insane, which is probably due to protracted and violent rubbing of the auricle. "Any portion of the perichondrium may be involved, but it is usually limited to a small space. Thickening is often scarcely observable, and to the feel it is not 'doughy.' The deep-seated nature of the inflamed or congested region, however, may be discovered by stretching out the auricle between the observer's eye and a strong light. The effusion is not sufficient to form a tumor: such cases seem to present the characteristics of the first stage of othæmatoma." The author then describes a case he has recently observed.

Treatment.—It is laid down as a safe rule not to be in haste to interfere unless rupture of the sac be imminent, since in a certain number of cases a manifest tendency to spontaneous recovery exists. It must also be remembered that, whatever the supposed cause or causes, we are dealing with a perichondritis, "in the treatment of which we should be guided rather by its character than its causes." And, furthermore, one should be guarded against the strong tendency to operate and interfere in these cases. Whenever these tumors have been treated like abscesses, by incision, poulticing, and stimulating lotions, the results have been almost invariably unfavorable, since gangrene, carious destruction of the cartilage, and, not rarely, death has been the end. (Dr. Wallis, 1884.)

Wallis then fell back on nutritious diet, mild cathartics, and local applications of lead-water, treating the affection like *noli me tangere*. This treatment continued for weeks was successful in a number of cases. Fisher and Marcé pursued purely an expectant plan of treatment. Sexton declares othæmatoma to have an aggressive and regressive period. In the former the observer is seldom offered a chance of observing the incipient symptoms. Usually a tumor is found to exist, and the surgeon is called in to limit its extension if possible.

"If it is found that the serous or serosanguinolent exudation is not active, and that the quantity already present is not great, we may prescribe rest for the patient, and administer small and frequently-repeated doses of the tincture of aconite-root, with a view to arrest the activity of the circulation about the head. Locally the affected region, and beyond even, may be enveloped with a coating of collodion,

the gentle and uniform pressure produced by its contraction acting as a compress, and thus promoting absorption."

In resorting to methods to increase absorption, care must be exercised lest they increase unduly the local irritation. When the tumor is large and contains a considerable clot, it is best to incise it and cause the contents of the sac to escape. To prevent refilling, a seton is recommended. As the secretion lessens, its removal will be best accomplished by aspiration. Adhesive inflammation is much better accomplished by massage than by the old method of irritation by a seton.

GUMMA OF THE AURICLE.

Partial necrosis of the cartilage of the auricle, as a consequence of an ulcerating gummatous tumor of that part of the ear, is extremely rare, if we are to depend upon the testimony of medical literature. Hessler, of Halle, however, reports the occurrence of a case in 1881, in the *Archiv für Ohrenheilkunde*, Bd. xx., part i., 1884.

The patient exhibited an ulceration in the concavity of the concha of the right ear. This spot, after suppurating for some days, healed spontaneously. Before the suppuration occurred, the auricle became swollen and enlarged, bluish red, and burning, and so painful that the patient could not lie on that ear and sleep. At the first inspection of the ear, the auricle, besides this bluish-red, swollen, and shining appearance, was double the size of the left auricle and stood out almost at a right angle from the side of the head. The furrow in the skin behind the auricle had entirely disappeared, and the skin of the mastoid was swollen and tight. The skin in front of and below the ear was also swollen and very sensitive to the touch.

Upon the anthelix and in front of its division into the crura furcata there was a sore about three millimetres in diameter, the edges and surface of which were yellow and moist, and which discharged a serous matter, yellow and thick.

The auditory canal was uniformly contracted throughout its entire extent, but a small speculum could be introduced and the membrana tympani thus inspected. The latter appeared normal; the hearing was unaffected.

At first sight the affection was very naturally supposed to be syphilitic; but a further examination failed to confirm this opinion, as the rest of the body manifested no trace of syphilitic taint. The patient confessed that, four years before, he had had an ulceration of the penis, in conjunction with gonorrhœa, but said that this had been promptly healed by internal medication and local treatment, without any secondary manifestations. He had not observed at any time since any trace of cutaneous eruption, nor any affection of the mucous membrane of the fauces. In the absence of any trace of syphilis, it was not deemed advisable to establish a specific treatment, especially since medical literature has not presented any case of gummous tumor of the auricle without simultaneous symptoms of syphilis elsewhere on the body. Hence the treatment of the inflammation was limited to the application of compresses of cold lead-water (*eau blanche*). Subsequently the ulcer was cauterized every fifth day with lapis infernalis. The swelling and the sore soon diminished, but the latter did not cicatrize. Some days later the patient returned, with his ear in the condition of the first visit, excepting that the sore was larger and more extended. A second course of treatment, supplemented by incisions in the anterior part of the auricle and injections of a three-per-cent. solution of carbolic acid, with further cauterization by means of lapis infernalis, failed to have any effect. Nor did a course of baths prove beneficial, since the patient returned home worse than when he went away.

After six months of treatment, there finally appeared on the right tibia an enlargement the size of a German mark, rounded and hard to the touch, painless, and completely detached from the bone. No cause could be assigned for its appearance, and it soon became apparent that it must be referred to a syphilitic origin. A course of treatment by iodide of potassium caused both the affection on the tibia and on the auricle to disappear.

It was learned subsequently that, two years before, this patient had been treated for some time, and without success, by a system of bandages, for an enlargement of the joints of the hands, which, however, had not been attributed to syphilis; and, finally, he had been successfully treated for a gummous orchitis by means of iodide of potassium. The syphilitic cause of his auricular disease now remained no longer doubtful.

The case is remarkable by the fact that the aural affection was isolated from all other symptoms or traces of syphilis, and appeared as a tertiary symptom of the disease. This furnishes a demonstration in favor of the specific character of new local formations in persons affected by syphilis, and shows the necessity of treating them, like the original disease, by means of a strictly specific medication.

(To be continued.)

THE ACTION OF THE SULPHATE OF QUINIA ON THE BLOOD.

BY HOBART A. HARE, M.D.

WHILE it is generally agreed that quinia instantly stops the migration of the white blood-corpuscle on the stage of the microscope, it has been argued by many that the drug does not prevent its migration in the body.

For the purpose of coming to some definite conclusion in regard to what the action of the drug really was, I carried on four series of experiments, using twelve Cohnheim frogs in each series.

In order to provoke migration, I used the point of a hot needle, which was applied and instantly withdrawn.

As all results would be negative unless the blood-vessels observed were of the same general size in every case, I never watched an arteriole over three millimetres or less than one and one-half millimetres in diameter, the average diameter of the vessels being in all four series two and a fraction millimetres.

In the first series I counted the migration from the vessels when there was no inflammation and no drug present. I found that in twelve frogs the migration in thirty minutes only averaged three.

In the next series, in which I caused inflammation in the manner stated, I found that in twelve frogs the migration in thirty minutes averaged twenty-nine.

In the third series, to which I gave ten grains of the quinia hypodermically, the migration averaged 1.4 in thirty minutes.

In the fourth series, where I caused inflammation and gave ten grains of quinia hypodermically, the migration did not take place at all in five of the frogs, two corpuscles migrated from two of the frogs, and from the other five only one migrated in thirty minutes, so that the average was virtually none at all.

These series would prove that the corpuscles are stopped in their migratory movements by the drug, at any rate in regard to passing through the wall of the blood-vessel.

Whether the drug does this by a direct action on the corpuscle or not is another question.

To discover in what way the drug stopped the migration,—that is, whether the corpuscle itself was influenced, or whether the blood-vessel wall was acted on,—I instituted the following observations:

Causing inflammation and administering the drug, I noticed that the corpuscles stopped at the irritated point and congregated, but did not pass through the wall as they did when there was no drug but simply inflammation present; and *this* difference existed, viz., that where inflammation was alone present the walls were dilated and therefore thinner, but where the drug was present also the walls were contracted. This contraction could not only be seen by the eye, but was marked by the use of the eye-piece micrometer.

To cause this contraction the drug must act either on the vaso-motor system or the muscular coat of the blood-vessel wall.

In order to see if the contraction of the blood-vessels was due to centric vaso-motor stimulation, I made a section of a frog's spinal cord high up and found the contraction was still present, and in another frog, to whom quinia was given after section was made, the contraction took place. This proves that the action is not centric. The only remaining action which it could have is on the peripheral vaso-motors or the muscular fibres in the vessel walls. According to Prof. H. C. Wood, atropia in toxic doses probably paralyzes the muscular coat. I therefore gave a frog one-sixtieth of a grain of atropia, and saw an arteriole dilate, thus proving one-sixtieth of a grain of atropia to be a toxic dose to the frog. Another frog was taken, inflammation caused, quinia given, then atropia, and the contraction caused by the quinia remained. This would seem to prove peripheral stimulation; but this is not at all tenable, for if atropia paralyzes the muscular fibres, the stimulated peripheral endings could not cause contraction.

The only explanation seems to be that

the quinia acted on the fibres themselves to such an extent that it antagonized the atropia.

My observations in regard to the effect which section of the cord would have on vaso-motor contraction are directly opposed to those of Jerusalimsky, who asserts that the contraction is not present after section is made. Schroff found that in the cinchonized animal neither galvanization of a sensory nerve nor asphyxia produced contraction, claiming with Jerusalimsky that there was paralysis of the whole vaso-motor system, as I understand them. Heubach found *no* paralyzant action of this kind when he used galvanization of a sensory nerve. To prove, then, that quinia has no paralyzant action of this kind, I took a frog and strapped him to the frog-plate by placing a very strong and tense rubber band over the windpipe, and in order to prevent his using his skin as a means of respiration I allowed it to become dry. On examining his mesentery, I found no paralysis present at all, and the arterioles evidently very much contracted, as if by the action of the stimulated vaso-motors combined with a direct action of the drug on the muscular coat. It therefore seems proven to me that the drug does not paralyze the vaso-motors either peripherally or centrally, and probably has no action on them at all, unless it be *perhaps* very slight stimulation, which I doubt, any contraction of the vessel being due to the action of the drug on the muscular coat. It seems to be decided that quinia does also decrease heart-power, as nearly all observers agree in this respect,—that is, in toxic doses.

I shall consider therefore proven,—

1st. That the sulphate of quinia does not cause paralysis of the vaso-motors.

2d. That the contraction, when the sulphate was administered during inflammation, was produced by a direct action on the muscular coat of the blood-vessel, and was independent of any vaso-motor action.

3d. That the drug does prevent the migration of the white blood-corpuscle in the body, particularly when inflammation is present.

4th. That this stoppage of migration is due not to any action on the corpuscle itself, but to the contraction of the muscular coat and the decreased heart-power. Because if you have a dilated vessel you must have a thin wall, and if you have a strong heart you have both the *vis a tergo* of the circulation and also the decreased resistance of the wall in so thin a state, and consequently the corpuscles migrate readily.

If you give a drug which causes both decrease in that heart-power and contraction of that inflamed blood-vessel, you no longer have that *vis a tergo* so strong, nor the doors of migration so wide open. Briquet, A. Eulenberg, and Schlockow have all shown that large doses of quinia depress the heart and cause its stoppage in diastole. In two frogs' hearts which I immersed in a solution of quinia I also got stoppage in a very short time in diastole. It seems rather difficult to reconcile the two facts that quinia should have such a depressant action on the heart-muscle, which, though striated, is virtually involuntary, and yet seem to have a stimulative action on the non-striated muscular fibres in the blood-vessel walls. No explanation can be offered of this other than there being some depressing action on the heart's contained ganglia.

Bonour, Arvedi, Baldwin, Melier, Monneret, and Magendie state that the blood after death from toxic doses of quinia is dark, defibrinated, and non-coagulable. Briquet, on the other hand, states that it is not as the others state, but just the contrary.

Taking three rabbits, I gave them three different doses respectively, as follows: to the first, one hundred and twenty grains, hypodermically; to the second, one hundred grains; and to the third, seventy-five grains.

In every case the blood clotted very rapidly and firmly in the vessel it was caught in, and there was a clot in the soft, flabby heart.

It may be well to state that the temperature of the surrounding atmosphere during the observation of the frog's mesentery was never allowed to vary more than five degrees Fahr. The observations were always made at the same time of day, and the frog was thrown away after his mesentery had been exposed thirty minutes, as diapedesis was set up after that time by the abnormal exposure of the parts. The water used to keep the mesentery clean was of uniform temperature also. The rabbits were young and healthy, and were kept in a room of good size, with plenty of food, light, and air.

OLEATE OF ACONITIA IN OPHTHALMIC PRACTICE.

BY ALBERT G. HEYL, M.D.,

Ophthalmic Surgeon to the Episcopal Hospital.

I DESIRE in this paper to place on record some clinical experience in connection with the use of oleate of aconitia in ophthalmic practice. The preparation used contained two per cent. of the alkaloid. It was generally applied to the skin of the upper lid, over a surface equal to the area of a ten-cent piece. The effect was local. About an hour after the application, a sensation of heat would be experienced; then profuse lachrymation would occur, the tears escaping freely through the nostril of the same side. The effect lasted for a varying period of time. Generally several hours would elapse before the effect ceased. I have, however, known it to subside in an hour. The following cases will give illustration of its therapeutic action:

Case I.—A Swedish sailor, who, about a week before his arrival at this port, noticed something wrong with his R. E., on the arrival of the vessel came under my care at the Episcopal Hospital. The L. E. was normal. The iris of the R. E. widely dilated, the power of accommodation annulled, but distant vision good. The patient was a vigorous man of 30 years of age, without any evidence of general disease. There was a history of a slight urethritis. The pupil was very easily influenced by eserine: even a solution of $\frac{1}{30}$ grain to f℥j would temporarily contract the pupil, and with a stronger solution the ability to see a few inches from the eye could be brought about. As soon, however, as the remedy was suspended, the eye would return to its previous state. There was a seething sound in the right ear, evidently depending on the same cause as the eye-trouble; also neuralgic pains over the right half of the head, with tenderness on pressure over the supra-orbital foramen. Optic nerve looked a little whiter than normal; the retinal veins seemed to be abnormally large, while the arteries were of normal calibre. The small venules running into the retinal veins were visible, but corresponding arterioles were absent. Fowler's solution in small doses was given, but was followed by the occurrence of a simple continued fever. The arsenic was stopped, and under appropriate treatment the fever subsided. After a proper interval, the arsenic was again given, with a recurrence of the febrile disturbance. Evidently there was either an idiosyncrasy in this phenomenon or the abnormal state which gave rise to the eye-trouble was the cause of it. The tinct. aconit. rad. was given, and apparently through it the accommodation partly returned, the patient being enabled to read Jaeger 11 at about ten inches. No further progress seemed to be made, and the oleate of aconitia was employed. The effect was as follows: I saw him about two hours after the application. There was profuse lachrymation, pupil perhaps slightly contracted. An hour later, lachrymation still continues, pupil is contracted not circularly, but is heart-shaped. Iris is injected. Superficial conjunctival vessels, perhaps veins, are injected. The large subconjunctival veins corresponding to the horizontal and vertical meridians were also injected. The eye did not seem sensitive to light; there was a good deal of winking, presumably due to the tears. No change was induced in the accommodation.

Cases of this kind are well known clinically, although their pathology is obscure. In my opinion, this was not a case of paralysis of the iris and ciliary muscle, except perhaps in a very restricted sense. It is true that both loss of accommodation and dilatation of the iris existed, but by the use of eserine they could be brought back. The fifth pair of nerves probably stood in some causal relation to the eye-trouble. It is noteworthy that, while slight, irregular contraction of the iris was induced by the aconitia, no change in the accommodation was observed. On the other hand, the internal use of the tincture of aconite seemed to be followed by considerable improvement in the accommodative power.

Case II.—W. G., æt. 34. Sent to me by Dr. F. L. Haynes. This patient had been struck on the L. E., sixteen hours previous to my seeing him, by a flying bar of hot iron. Atropia had been instilled and hydrate of chloral given internally. When I saw the patient there was intense pain about the eye. A superficial eschar about three-fourths of an inch long by one-sixteenth broad existed in the skin of the upper eyelid; the latter was purple from venous engorgement. The media were cloudy. By reflecting the light into the eye, a number of dark lines were seen, probably due to wrinkling of the anterior capsule. The retinal arteries were very tortuous. R. E. could not be examined satisfactorily at this time. A day or two later this was examined again, and the same arterial tortuosity observed as in the L. E. Pressure on the left supra-orbital nerve induced a sensation like that of a foreign body rolling in the eye. Morphiæ sulph., gr. $\frac{1}{8}$, internally, night and morning, was ordered, and also the oleate of aconitia to be applied in the neighborhood of the eye. In a few days there was complete

relief of the pain, and the patient was discharged.

Case III.—Miss B. came to my office February 1, 1884, with the following history. Within a few days the skin about the left orbit had been cut by pieces of broken window-glass. The wounds had healed, leaving two small scars, about on a level with the infra-orbital ridge. The eye was very sensitive to light, although not injected. The retinal arteries in each eye showed the tortuosity common in cases of so-called irritable retina. Pressure on the scars would cause the lids instantly to close. The patient further suffered from false projection: that is to say, in looking with the left eye at an object near at hand, it would appear much farther away from the patient than it really was. This I suppose was due to some defect in the process of accommodation. Both internal treatment and local applications of chloroform-liniment about the eye were ordered. A weak solution of eserine was also applied. No material relief was thus obtained. The oleate of aconitia was then applied to the scars, with the effect of both relieving the patient and at the same time seeming to cause the cicatrices to disappear.

In both of these cases there was undoubtedly lesion of the peripheral ends of the fifth pair. Some doubt may be raised as to the effect of the aconitia in relieving Case II., as morphia was given at the same time. My impression, however, at the time was that the aconitia was really the efficient agent. Case III. was less open to doubt: here was a patient whose trouble was beyond a doubt caused by the cicatrices in the skin, under observation for months, treated with slight effect by various remedies, and finally relieved by the local use of the aconitia. This case seems to point to this conclusion,—viz., that in abnormal conditions of the fifth, depending on lesions of the peripheral ends, as from scars in the skin, etc., the aconitia will do good.

There are certain cases of ciliary neuralgia which are relievable, in my experience, with the oleate of aconitia, and perhaps the true explanation of such cases is found in a peripheral lesion of the fifth, although invisible to the naked eye.

Graefe's classical case of cure of blepharospasm by section of the supra-orbital nerve is well known, and may be studied in connection with the above cases. In this case the exciting cause was a blow from a missile apparently inducing such change in the peripheral nerve-filaments as to set up reflex spasm. There are, however, cases of ocular pain which are not reached by the aconitia. Thus, a patient who suffered with great ocular pain and great intolerance of light, and in whose eyes decided pigmentary change in the outer layer of the retina was observed, received no benefit from the aconitia. The fifth pair was involved in some way in this case, but the aconitia seemed to produce no effect.

1535 Pine Street.

TRANSLATIONS.

The Effects of Bromoform, Bromethyl, and Bromethyline.—Bonome and Mazza, from a series of physiological experiments recently conducted in the laboratory of Prof. P. Albertoni, in the university at Genoa, obtained the following results: 1. *Bromoform* is a general anæsthetic. Dogs and guinea-pigs almost always show the same symptoms of anæsthesia and muscular relaxation, following inhalation, that the human subject does. In five experiments upon men, three were well narcotized, lasting even for a whole hour; in two (probably on account of the use of a defective preparation containing free bromine) there was no narcosis, but, on the contrary, irritation of the conjunctivæ, a flow of tears, burning in the eyes, etc. The narcotic action they believe to be a little slower in appearing than when chloroform or ether is used, but the success is apparently the same as with both of these valuable anæsthetics.

2. The narcosis obtained from the inhalation of bromoform is free from the stage of exaltation which we are called upon to witness during chloroform-administration. On this account preference should be given this agent in case the patient is subject to epilepsy or alcoholism. Billroth and Nussbaum have each directed attention to the danger of exciting attacks in epileptics by the use of chloroform. This does not occur during the use of bromoform, which allays the irritability of the cerebral cortex.

3. Bromoform does not disturb the respiratory function, but after prolonged narcosis there is a slight reduction of the blood-pressure. The respiratory fluctuations of the blood-pressure in the course of the narcosis are very regular; the pulse remains strong. In none of the dogs which

inhaled it did the bromoform cause sudden arrest of the heart's action, such as is seen during the use of chloroform.

4. During the bromoform narcosis, while it was noticed in dogs that there was decided mydriasis, in man there occurred only trifling alterations of the pupil; there was neither nausea nor vomiting. The quantity of bromoform required to produce complete narcosis is less than that of chloroform as it is commonly used.

5. In the first few hours after narcosis, it was noticed that there was a sinking of the temperature exactly as after chloroform; but the patient appeared to recover sooner from its effects.

6. Given by the mouth, bromoform also acts as a hypnotic and anæsthetic.

7. Moreover, bromoform prevents putrefaction in organic substances (urine and meat); bacteria are not developed in the presence of bromoform.

8. Injected under the skin, bromoform is fatal when given in a dose of 0.15 gm. for every 100 gm. of the bodily weight.

Ethyl bromide produces narcosis more quickly than chloroform or bromoform, but is more easily eliminated from the system, and, on this account, its effects are more temporary. It is to be recommended for short operations. It is less active than bromoform, and becomes poisonous at a point of each 0.17 gm. for 100 gm. of the bodily weight. Whilst the narcosis reduces the blood-pressure (20–30 mm.) at first, it rapidly increases again after the termination of the narcosis, when the respiration also is accelerated. Bromide of ethyl also reduces the irritability of the cerebral cortex, and likewise hinders the development of bacteria in organic infusions.

Ethylene bromide does not produce complete narcosis upon inhalation, but, when pushed, causes fatal results by abolishing the cardiac activity.—*Centralblatt für Chirurgie*, No. 36, September 6.

Counter-Prescribing in France.—An interesting case has just been adjudicated in Rouen. The law forbidding grocers to deal in pharmaceutical products, Eustache, a grocer of St.-Étienne, was arrested for selling castor oil at retail. The court decided—not very logically, it would seem—that, castor oil not being a pharmaceutical product, grocers might sell it; but, at the same time, they must sell it in commercial quantities and not in medicinal doses. Inasmuch as the unfortunate grocer acknowledged playing the rôle of the pharmacist, he was found guilty and compelled to pay five hundred francs fine.—*La France Médicale.*

Hysterectomy for Uterine Cancer.—In a recent discussion of the treatment of carcinoma uteri by extirpation of the uterus, before the Academy of Surgery, most of the surgeons agreed with the opinion expressed by Verneuil and Polaillon, that "hysterectomy would be a very good operation at the beginning of cancer, if it were less dangerous; but with the progress of surgery its dangers may be lessened. It is, therefore, an operation for the future; but under the present conditions, the mortality being one in three, the surgeon has not the right to resort to it, because fortunate results from it are far from being frequent."—*Bull. Gén. de Thérapeutique*, September 15.

Treatment of Eczema of the Scalp.—M. Doyon recommends the following in infantile eczema of the head:

℞ Acidi salicylici, 1 gr.;
Tincturæ benzoini, 2 gr.;
Olei petrolei, 50 gr. M.

When a firmer preparation is needed, having a more drying effect, he uses the following in preference:

℞ Acidi salicylici, 2 gr.;
Olei petrolei, 50 gr.;
Zinci oxidi,
Amidon, āā 25 gr. M.

To be applied to the excoriated surfaces and retained with a compress of wadding. It need not be disturbed for several days unless the secretion is free, in which case it is to be changed daily.

Effects of Removal of the Thyroid Gland.—Dr. Zesas claims (*Wiener Med. Wochenschrift*) that the thyroid gland is supplementary to the spleen in its hæmatopoietic functions, and that its removal is followed by an excess of white corpuscles in the blood. From experiments upon animals the statement is made that removal of both thyroid gland and spleen invariably causes death. It is also said that thyroidectomy is followed by nervous disorders, without actual paralysis, but with sluggish movements, fibrillary contractions, tremor, and even tetanus. Zesas therefore denounces the operation as an unjustifiable one.

EDITORIAL.

TEA AND COFFEE.

THE physiology of food is always interesting, especially when therapeutic applications are suggested. In the *Ephemeris* for September, Dr. Squibb communicates the results of some recent analyses of tea and coffee, which are worthy of note. Without discussing the method of analysis pursued by the experimenter, we will give some of his results. The following varieties of tea, obtained from wholesale dealers, were assayed in order to ascertain the best variety for use in making a standard fluid extract for medical use.

A fancy, high-flavored Formosa Oolong, eighty-five cents per pound, contained 3.10 per cent. of caffeine.

Extra fine small leaf gunpowder, sixty-five cents per pound, contained 3.51 per cent. of caffeine.

Formosa Oolong, fifty-five cents per pound, contained 2.80 per cent. of caffeine.

Formosa Oolong, forty-five cents per pound, contained 2.74 per cent. of caffeine.

Basket-fired Japan, forty-four cents per pound, contained 2.80 per cent. of caffeine.

Basket-fired Japan, forty cents per pound, contained 2.87 per cent. of caffeine.

Amoy Oolong, large leaf, twenty-five cents per pound, contained 2.95 per cent. of caffeine.

Congo, large, coarse leaf, North China, twenty cents per pound, contained 2.41 per cent. of caffeine.

This series embraces representatives of the tea market from the very highest to the very lowest prices and qualities. Teas sold below twenty cents per pound are said to be mere dust or refuse from better grades, or imitations of tea made from other plants.

It will be first noticed that the yield of caffeine does not vary as much as might be expected, and really varies comparatively little; and, next, that the disparity between the caffeine value and the money value is very great. The two values bear only a general relation, which is much confused by exceptions. The highest-priced tea does not contain the most caffeine; while the next to the lowest in price ranks third in the proportion of caffeine. The lowest-priced tea of all contains within .7 per cent. of caffeine of the highest.

This result showed that some other element than caffeine gives value to tea, probably the aroma or flavor, although from a medical stand-point the yield of the alkaloid is probably the best measure of the value yet reached. It was concluded that the extra gunpowder tea was the best source of a fluid extract for therapeutic use, because it yields about one-fifth more caffeine than the basket-fired Japan, which would be the next choice. The standard strength of the fluid extract of camellia recommended is that yielding 3.5 per cent. of the alkaloid, the adult dose being fifty minims, or a small teaspoonful. It is best given in ice-water. From a long course of physiological testings, it was determined that there was, beyond a sense of well-being and a general toxic effect, no influence upon secretions or excretions, and especially no after depressing effect, observed from either tea or coffee. It does not appear whether an estimation of the daily excretion of urea, or nitrogen, was made or not; it is not probable, however, that the well-known physiological effects of tea and coffee in reducing the excretion of urea (established by Lehmann) are referred to in making this statement, but merely the general action upon quantity and appearances of the secretions.

With coffee a similar assay was made of the principal kinds obtainable in the market, as follows:

Mocha, an Arabian coffee, twenty-three cents per pound, yielding 1.05 per cent. of caffeine.

Mocha, seventeen cents per pound, yielding 1.07 per cent. of caffeine.

Mandheling Java, twenty-three cents per pound, yielding 1.30 per cent. of caffeine.

Mandheling Java, twenty-three cents per pound, yielding 1.22 per cent. of caffeine.

Interior Java, seventeen cents per pound, yielding 1.10 per cent. of caffeine.

Maracaibo, eleven cents per pound, yielding 1.20 per cent. of caffeine.

Rio, strong and rank, eleven cents per pound, yielding 1.00 per cent. of caffeine.

Rio, ten cents per pound, yielding 1.05 per cent. of caffeine.

Dr. Squibb remarks that the same disparity between market value and yield of caffeine is observed here as in the case of tea, but the caffeine value is much more uniform than in tea. The difference between the extremes is here only .3 per cent., while in tea it is 1.1 per cent., the tea yielding on the average less than two and a half times the amount of caffeine.

The value of the aroma in coffee is fully considered, but, curiously enough, no part is given to the aromatic oil in estimating the strength or therapeutical effects of the coffee. Comparing effects to determine their relative therapeutic value, the fluid extract of roasted coffee made like that of camellia was found to contain 1.68 grains of caffeine in each two drachms, which was equivalent in physiological effect to three grains of pure caffeine, or to one hundred and eighty minims of fluid extract of coca, to seventy minims of fluid extract of tea, to sixty minims of fluid extract of guarana, or to one hundred and fifty minims of fluid extract of green coffee. The adult dose would be about forty minims, equivalent to one grain of caffeine, to be gradually pushed to its full physiological effects. A cup of good Java coffee was found to contain 2.78 grains of caffeine, which was found to be in effect equivalent to five grains of pure caffeine, or nearly double the single maximum dose of the German Pharmacopœia. So that in some the dose above given may be considerably increased; and this would undoubtedly be the case were the person accustomed to the use of tea or coffee as a beverage.

PROFESSOR WILLIAM OSLER.

THE election of William Osler, M.D., of Montreal, Canada, by the trustees of the University of Pennsylvania to the chair of Clinical Medicine in the faculty of that institution, on the 7th instant, is a well-merited compliment to him and a substantial recognition of the merits of a rising man. Dr. Osler, having pursued his medical studies at the McGill College, Montreal, and at the Toronto School of Medicine, received the degree of M.D. in 1872, and subsequently he attended lectures at the University College, London, and in Berlin and Vienna. In 1874, upon his return from Europe, he was chosen to fill the chair of Institutes of Medicine in McGill College, and subsequently was appointed Pathologist to the Montreal General Hospital and Lecturer on Clinical Medicine in the summer session. He is a Fellow of the Royal College of Physicians of London, and President of the Canada Medical Association. His contributions to medical literature, though not voluminous, are characterized by originality and scholarship, and have already won for him enviable distinction. We tender Dr. Osler a hearty welcome, and assure him that he will find in Philadelphia many friends who already know him by reputation, and who will cordially greet him as he enters upon his new duties among them.

WE regret to hear that, on the day after Prof. Mallet came to Philadelphia, most of his household goods were destroyed in the burning of a storage-warehouse. We hope, however, that this will prove a good omen, as we recall the fact that the late Prof. Gross met with a similar loss shortly after his arrival, and he subsequently remained here for life.

HENRY C. LEFFMANN, M.D., has just been elected Demonstrator of Chemistry at the Jefferson Medical College.

LEADING ARTICLES.

PECULIARITIES OF CONFORMATION IN THE SKULLS OF CRIMINALS.

DR. JOHANN BADIK, a disciple of Benedikt's, has during the past ten years occupied himself with the question of the anomalies of the skulls and brains of criminals. His investigations have been conducted in the great Hungarian prison at Illava, of which he is the physician, and the results are published in a recent number of *Virchow's Archiv.* At Illava are imprisoned all offenders in Hungary sentenced to terms exceeding ten years, in number more than six hundred, and including those convicted of theft, burglary, murder, arson, counterfeiting, and the like. Truly a fine field for studies of this kind.

The investigations have been directed especially to the skulls and to the anomalies of function of the central and peripheral nervous systems. As regards the skulls of criminals, he found as highly characteristic,—1, flattening posteriorly, with low position of the external occipital protuberance; 2, asymmetry, and, 3, in consequence of this, a difference in the size and position of the foramina transmitting the blood-vessels. The anomalies of function of the nervous system, central and peripheral, consisted of a progressive series of exaltation- and still more of depression-states, as well of the intellectual life as of the activity of the nervous system, with all their resulting phenomena.

The lesions of the brain and its coverings, as found post mortem in some sixty or seventy cases, consisted of scattered areas of translucency in the calvarium; in a few cases local adhesions between the dura and the arachnoid, the latter presenting a gray appearance, through which showed the dilated blood-vessels of the pia. In the arachnoidea and pia, and in the sulci, was collected an opaque fluid of the consistence of glycerin. Upon puncture of the arachnoidea this fluid escapes slowly from the subjacent sulcus, but not from the sulci immediately adjacent,—a sign that the membranes are adherent to the summits of the convolutions. The pia, grayish in color, cannot be detached from the brain without injury to the latter, and shows, besides dilated blood-vessels, many scarcely noticeable adhesions, which extend into the sulci, and by uniting the contiguous parts of the gray matter tend to obliterate the furrows. The gray substance is less deep, but of a firmer consistence, than normal. The white substance shows no gross abnormality. The ventricles contained in only one instance an increased quantity of fluid.

Dr. Badik classifies criminals into four typical groups, a division based upon the association of certain mental and moral qualities with definite abnormalities in the skull and corresponding lesions in the brain and its coverings. From the anatomical stand-point these groups arrange themselves into two classes: 1, those with symmetrical skulls; 2, those with asymmetrical skulls. There are then under

I. SYMMETRICAL SKULLS.

A. *The small (undeveloped) skull, without pathological changes, either in the brain, which is correspondingly small, or in its membranes.*—That the possessors of these brains are simple-minded persons, concerning whose lack of mental development and of intellectual capacity there could be no question, is obvious. They are, as a rule, good-natured inmates of the institution, who can be employed only at the most indifferent occupations, uneducated and incapable of education. Consequently they depart from prison, after having served out their term of punishment, in the same mental condition as that in which they entered it. They are not in a position to understand either the gravity or the consequences of their offences, and they are equally indifferent to their punishment. They are usually great feeders. Unable to comprehend the importance and results of evil deeds, and having no idea of morality, religion, or law, they commit crime in pure simplicity, or as the tool or associate of other miscreants. Their want of moral perception leads them ever to the commission of new offences when permitted to go at large.

B. *Skulls of medium development, with the above-described lesions of the brain and its membranes.*—To this group belongs a considerable but by no means the largest number of offenders. Its members are intellectually more developed, and comprehend the nature and consequences of their crimes. Their behavior in prison is, as a rule, good. They endure their

punishment with patience, occasion little trouble, and afford no bad example to their fellow-prisoners. As a rule, these individuals leave the prison improved mentally and morally, and are practically never recommitted for further offences. They suffer much from neuroses of the vascular system, complain much of headache and dizziness. The abnormality of the nervous system expresses itself in the motor sphere in two ways: they either display great strength or they cannot be induced to work, alleging the most varied pretexts as the cause of their laziness. Their crimes have been usually committed in states of intense emotion, by reason of jealousy, hunger, in the defence of their rights and possessions, revenge, or in vindication of their outraged honor, etc.

II. ASYMMETRICAL SKULLS.

Here the corresponding lateral parts are unlike in position and size.

C. *The brain and its membranes show no pathological changes.*

The majority of the inmates of the prison present this skull-malformation.

Of the gravity of their crime, which is usually great, they have little idea. Their thoughts are usually occupied with evil, and their deeds are correspondingly bad. They are liars, slanderers, swindlers, scamps, and withal trifling and shameless. There is no evil that they are incapable of planning and committing. They are usually leaders in crime, who urge on and instruct others, and also who stir up discontent, revolt, frays, and combats, who slander and bear false witness against their associates. They feel no repentance for past misdeeds, and by themselves or with their fellows are ready forthwith to rob, murder, or destroy, as may suit their purposes, without remorse, to commit villanies that are neither explicable nor comprehensible.

These are criminals who are benefited neither by instruction, nor by counsel, nor by religion, nor by punishment, who end the vicissitudes of a checkered career in prison.

D. *Asymmetrical skull, with pathological changes in the brain and its coverings.*—The character of criminals of this type depends wholly upon the lesions of the central nervous system. When the pathological changes are slight, the condition is analogous to that of criminals referred to C; when they are more advanced, not only are vascular neuroses present, but also epilepsy in its various forms. In truth, it is among criminals of this class that epilepsy in its most varied and terrible forms is seen. These are prisoners whose crimes have been committed for the most part (if not indeed always) in a state of perverted consciousness and are remembered only as a dream. The mental condition, always feeble, sinks at middle life into imbecility, and they are often paralytic. Anything like education is in these cases obviously out of the question. These criminals reach towards and often transcend the border-line between crime and insanity. The proportion of the four types at Illava was—A, 1; B, 3; C, 9; D, 0.5.

The criminal classes have claims upon society that are as yet imperfectly recognized. Self-interest joins with the highest motives in urging the close and searching investigation of the causes of crime from all points of view. These studies of Dr. Badik's, and others like them, will receive attention more widely than they will be at present accepted, especially in their more remote bearings. But we believe that it is by such investigations that the means will be found to reclaim many criminals, to proportionately diminish crime, and thus to benefit society at large. Neither the criminal class nor any other class stands wholly apart and antagonistic to society. The evil and the good form society, and betterment can only come by knowledge.

J. C. WILSON.

NOTES FROM SPECIAL CORRESPONDENTS.

SIAMESE THEORY AND PRACTICE OF MEDICINE.

ALL nature, according to the Siamese, is composed of four elements,—namely, earth, water, fire, and wind. The human body is supposed to be made up of these same elements, which are divided into two classes, visible and invisible. To the former belongs everything that can be seen, as the bones, flesh, blood, etc.; to the latter, the wind and the fire. The body is composed of twenty kinds of earth, twelve kinds of water, six kinds of wind, and four kinds of fire.

The varieties of wind are as follows: the first kind passes from the head to the feet, and the second variety from the feet to the head; the third variety circulates in the ar-

teries, forming the pulse; the fourth variety resides in the abdomen outside of the intestines; the fifth resides in the intestines, and the sixth enters the lungs in the act of inspiration.

The four kinds of fire are: first, that which gives the body its natural temperature; second, that which causes a higher temperature, as after exercise or in fevers; the third variety causes digestion, and the fourth causes old age.

The Siamese divide the body into thirty-two parts, as the skin, heart, lungs, etc. The body is thought to be subject to ninety-six diseases, due to disarrangement of the earth, wind, fire, and water. An undue proportion of fire causes fevers, and dropsies are caused by too great a proportion of water. Earth is supposed to produce disease by invisible and impalpable mists and vapors, and wind can cause all manner of complaints. Nine out of every ten natives, when asked what is the matter with them, will answer, "Wind." (Not long ago, on our way to Bangkok, we found a man dead upon the river-bank. The boatmen were speculating as to the cause of the man's death; but the oldest man in the company soon settled the matter by gravely remarking that, in all probability, it was due to wind.) It is thought that the external elements are constantly acting upon the elements composing the body, causing health or disease. Thus, in the hot season, the Siamese believe, we are more liable to fevers, and in the rainy season to dropsies, due to too great an absorption of water. Spirits are also supposed to have great power over our bodies, deranging the elements and thus producing all manner of maladies. One of our young men remarked not long ago, while travelling in a rather lonely portion of country, "I am not afraid of tigers, but I do fear spirits." The Siamese have numerous spirit doctors, and many are the propitiatory offerings made to the immaterial beings that fill the air.

In the time of Buddha lived one still worshipped as the Father of Medicine. To him, it is said, the plants all spoke, telling their names and medical properties: these were written in books, and have become sacred. If they fail to produce the results ascribed to them, the fault is never theirs, but is due entirely to want of merit in either doctor or patient. The natives use almost everything as medicine; the bones and skins of various animals occupy a large part of their pharmacopœia, while the galls of snakes, tigers, lizards, etc., are among the most valuable of their medicines. Most of the Siamese remedies are very complicated, being composed of scores of different ingredients. The following is an absurd recipe for snake-bite: A portion of the jaw of a wild hog, a portion of the jaw of a tame hog, a portion of the jaw of a goat, a portion of goose-bone, a portion of peacock-bone, a portion of the tail of a fish, a portion of the head of a venomous snake: these, being duly compounded, form a popular remedy when the venom has caused lockjaw. Burnt human bones, powdered and mixed with an equal portion of powdered alum, form a favorite medicine for sprinkling on ulcers. The eye-teeth of tigers, bears, lions, and various other animals (the more the better), ground up together, form the most popular remedy for fevers. The ashes of earthworms and human hair, mixed with cocoanut-oil, is frequently used for cuts. Every native physician has an image of Pra Ruse, the father of arts, in his house. All drugs are first placed in this idol's hand and receive his blessing; afterwards they are taken to the patient's house and boiled in earthen pots, a wicker-work star always being placed above and below the drugs, to prevent the spirits from tampering with them. In all fevers the doctor fills his mouth with some concoction and squirts it over the naked body of the patient in a fine spray, exactly as the Chinese laundry-men sprinkle clothes.

Dissection is never practised among the Siamese, consequently they are grossly ignorant in regard to the science of anatomy. The writer has not unfrequently seen them hew a body in pieces with a cleaver at least two feet long, but very little is ever learned from these rough post-mortem examinations. They are usually made with the expectation of finding one or more tumors in the abdominal cavity, which they suppose to be the work of witchcraft. They usually are successful in finding what they look for. Sometimes the spleen, at other times a kidney or some other normal organ, is mistaken for an abnormal growth inserted in the body by superhuman agency. The functions of the different organs are not at all understood. In the heart is supposed to be a cavity about the size of an almond. This cavity is thought to be filled with a fluid which changes its color and consistency with our passions. When we are calm and peaceful, this fluid is perfectly clear, like water; when we are angry, it is turbid; when very angry, it turns dark; and when we are in love, it is red. In stupid persons the apex of the heart is rounded, while in those possessing the usual amount of wisdom it is pointed. It is not known that the heart has anything to do with the circulation.

E. A. STURGE, M.D.

PETCHABURI, SIAM, June 2, 1884.

DRS. GRESSIN AND BOTARD, of Havre (*Union Médicale*), have made the interesting discovery that in the weever, or sting-fish (*Trachinus draco*, Linn.), and perch (*Trachinus vipera*), there is at the base of the dorsal spines a cul-de-sac which contains a gland secreting a poison. Injections of this glandular secretion into frogs, fish, birds, etc., caused pain, spasm, clonic convulsions, collapse, and death.

PROCEEDINGS OF SOCIETIES.

AMERICAN GYNÆCOLOGICAL SOCIETY.

THE Ninth Annual Meeting of the American Gynæcological Society was held in the city of Chicago, Illinois, at the Palmer House, on Tuesday, Wednesday, and Thursday, September 30, and October 1 and 2. Dr. Albert H. Smith, President of the Society, and Dr. William H. Byford, Vice-President, occupied the chair. The weather was favorable, and the sessions were well attended. The following-named members of the Society answered the roll-call: William H. Baker, M.D., Boston; Bernard Browne, M.D., Baltimore; William H. Byford, M.D., Chicago; Alexander Dunlap, M.D., Springfield; George J. Engelmann, M.D., St. Louis; Frank P. Foster, M.D., New York; William T. Howard, M.D., Baltimore; A. Reeves Jackson, M.D., Chicago; E. W. Jenks, M.D., Detroit; Joseph Taber Johnson, M.D., Washington; Richard B. Maury, M.D., Memphis; Paul F. Mundé, M.D., New York; C. D. Palmer, M.D., Cincinnati; Thad. S. Reamy, M.D., Cincinnati; John C. Reeve, M.D., Dayton; William L. Richardson, M.D., Boston; Edward Warren Sawyer, M.D., Chicago; John Scott, M.D., San Francisco; A. H. Smith, M.D., Philadelphia; T. Gaillard Thomas, M.D., New York; Ely Van de Warker, M.D., Syracuse; H. P. C. Wilson, M.D., Baltimore.

At various times during the meeting the following-named gentlemen were invited by vote to take part in the proceedings, and were made Members by Invitation: Dr. E. C. Dudley, Dr. W. E. Clarke, Dr. T. P. Seeley, Dr. N. S. Davis, Dr. Liston H. Montgomery, Dr. Ralph E. Starkweather, Dr. A. H. Burr, and Dr. George H. Randell, all of Chicago; Dr. P. McClure, of Dubuque, Iowa; Dr. Henry G. Dearborn, of Nashua, New Hampshire; Dr. J. H. Carstens, of Detroit; Dr. T. B. Harvey, of Indianapolis; Dr. Fritz Netzler, of Stockholm, Sweden; Dr. Frank Woodbury, of Philadelphia; Dr. Wesley M. Carpenter, of New York; Dr. W. H. Myers, of Fort Wayne, Indiana; Dr. J. H. Rauch, of Springfield, Illinois; Dr. J. K. Bartlett and Dr. William Fox, of Milwaukee; and Dr. T. A. Roger, of Montreal.

An ADDRESS OF WELCOME was delivered by Dr. WM. H. BYFORD, of Chicago.

THE PRESIDENT'S ADDRESS.

Dr. ALBERT H. SMITH, of Philadelphia, on Thursday morning, delivered the President's Annual Address, taking for his theme

THE PRESENT ASPECT OF THE PUERPERAL DISEASES.

After referring briefly to the benefits conferred by this Society upon the general field of medicine, not only by its actual work accomplished, as shown by its published Transactions, but also by the deeply-felt influence exerted upon the profession and upon the specialists in its several included lines of work, he passed to a consideration of the advanced condition of gynæcology, and to the comprehensive character of its labors, contributing, as it does, experimental knowledge, manipulative skill, and diagnostic accuracy, which are utilized in other departments of the art of medicine. Surgery especially is indebted to the labors of gynæcologists for extending by new operations its field of usefulness, for many ingenious instruments, and for the introduction of new methods of treatment which have added greatly to the means of the successful treatment of disease and injury. In abdominal surgery, the gynæcologist has had, from the beginning of its history, absolute control of the field, so far as the mass of work, the attainment of success, and the teachings through the medium of published results are concerned. Beginning with the surgery of the reproductive organs of woman at the pelvic brim, he has gradually been put in charge of all intra-abdominal diseases requiring surgical interference, without regard to sex or organ, and the operator who has established a reputation in ovariotomies and hysterectomies is now sought out for man, woman, or child upon whom an abdominal section offers the least hope of relief. Cases suggesting nephrectomy, nephrotomy, carcinomatous obstructions, invaginations, hydatids of the liver, cholecystotomy, all seek relief from the gynæcologist rather than the general surgeon. He himself had seen a man about to be discharged from the Woman's Hospital, Birmingham, having been successfully operated upon by Mr. Lawson Tait for biliary obstruction. Where, indeed, he asked, in the whole realm of general surgery can a claim be presented of statistics showing the barest approach to the actual life-saving operations or operations for restoration to usefulness of the maimed and helpless, as in the little domain of gynæcology?

The high standing of gynæcology and its services in the past invest the laborers in this department with special responsibility. He inquired whether or not the gynæcologists of America are sustaining their reputation by original work, by a high standard of literature, by maintaining an elevated tone in their department of medicine. He particularly urged upon the members of the Gynæcological Society attention to these important matters. He had been humiliated by the remark made last year by some transatlantic brethren, that a lowering of moral tone was observable in this country in the press and in the amphitheatre, and almost entirely in the productions of gynæcological writers and teachers. "We find in our best conducted journals articles devoted to subjects connected with the sexual relations, entering into minutiæ upon matters of no scientific value, and without special interest in themselves,

and rendered valueless, at any rate, by the character of the media of information through which these asserted facts are derived,—articles which can have no effect but to minister to a prurient and depraved taste, from which the members of our noble profession should be absolutely free. We find also articles coming from the pens of specialists in obstetrics and gynæcology attempting professedly to be moral homilies upon the family relation, based mainly upon the most exceptional extremes of married life, often the product of a morbid imagination in the writer, and being in themselves not only devoid of scientific bearing, but full of gross indecencies vulgarly told, and utterly unfit for the perusal of any class of readers."

Regarding this as one of the evidences of failure in earnestness for fair, honest work, he begged the Fellows of the Society to use all their influence to stop the flow of this foul current, which lowers the standard of purity of thought and befouls the sacred profession of medicine. There can be no fact in true science which cannot be fully developed by a man of pure mind without a shock to the most delicate: true science is embarrassed, not aided, by anything coarse or indecent.

The main subject of the address being the zymotic diseases, the speaker referred to the historical discussion which had taken place last year between Drs. Thomas and Barker, at the New York Academy of Medicine, upon "Puerperal Fever," and said that these two representative men might be considered as the exponents of two hypotheses as to the etiology of the disease, the one holding to "absorption" and the other to "essentiality," and, of course, advocating different methods of treatment based upon these views. In order to discuss the subject intelligently, he formulated the following definition of puerperal fever:

Puerperal fever is "a febrile condition occurring in a woman from two to four days after the termination of pregnancy, either at full term or prematurely, characterized by typhous symptoms, high temperature, and frequent pulse, the rapid formation of local centres of inflammation, suppuration and gangrene, metastatic abscesses, emboli, a violently phlogogenous condition of the blood, and, unless arrested, running on rapidly to disorganization and death." He believed that this definition would be accepted as based upon Dr. Barker's clinical reports of his cases, and yet meeting the demands of his most decided opponents. He then proceeded to consider the actual condition of the woman after delivery, which, if physiological, still is one which is easily converted into a pathological state from the results of traumatism combined with the hyperinosis of the blood and its tendency to determination to the pelvis.

After a review of the doctrine of the essentialists, he declared himself unable to accept the distinctions so carefully drawn by Dr. Barker in his work between the clinical cases of the disease, but saw in Dr. Barker's teachings an argument against crowding and hospitalism, and in favor of prophylactic measures.

Braxton Hicks attributes the puerperal-fever poisoning either to some modification of the scarlatinal or other exanthematous virus through the lungs, and its development after delivery, and, more recently, Dr. Kirkhead, of Galway, has advanced the idea of the interchangeability of all zymotic diseases into puerperal fever, which, after absorption, instead of reproducing themselves, appear with the characters of puerperal fever. As he could not conceive of such a change of type, he passed it without discussion.

He then took up the theories of the "absorptionists," (1) according to Semmelweiss (1847), who regards puerperal fever as a surgical fever, due to traumatism and septic purulent infection, or (2) according to Pasteur (1872), who attributes it to specific micro-organisms: in the words of Paul Bar, "No microbes, no puerperal infection." After a thorough consideration and comparison of these two schools of "absorptionists," a review of the phenomena presented by typical cases of the disease, and its pathological anatomy, he expressed his conviction that the teachings of Semmelweiss were more nearly conformable to the facts than those involving the specific germ, but still, in his own language, expressed a willingness, "when any one by repeated experiment proves the exact nature of the *causa morbi* present in every case, and never found except under conditions of similar character, then I will accept the *corpus delicti*, even if it be Pasteur's diplococcus and *microbes en chapelet*, and honor him the more for his pertinacity in maintaining his ground." In the same position as himself stand our principal English and American teachers,—Playfair, Leishman, Simpson, Goodell, Howard, Chadwick, Engelmann, and, less positively, Dr. Thomas and Dr. Barnes.

He then proceeded to an exposition of the recent teachings of the specific-germ theorists, and concluded that their claims had not yet been substantiated by actual demonstration. Criticising the statement of Pasteur that a germ cannot enter a healthy body, the blood is "firmly closed" against it, he asked, very pertinently, how can it then be a pre-existing cause of disease in that body? and declared that the woman is already infected who gets microbes into her circulation. That microbes are found in the lochia of every parturient woman no competent observer will deny, but he claimed that "every form that is found in the blood in the most virulent cases is found in the vagina of a healthy woman who remains healthy." He did not, however, wish to be understood as considering

these microbes as harmless: they may be carriers of infection, and they may obstruct the vascular spaces mechanically. He protested, however, against confining our attention to the microscopic examinations of the lochial discharges, when they should be given to the general condition of the patient. As to treatment, he advocated the methods endorsed by experience, rather than the new methods based upon antiseptic theories. He avoids overcrowding, and insists upon strict cleanliness and the use of vaginal douches of carbolized water, or, preferably, good fresh Labarraque's solution, or of hot water, 115° F., with mercuric bichloride 1 to 1000. He had no fear of intra-uterine injections, and always used them where there are any clots in the uterus or there is undue patulousness of the os uteri. There should be no air in the syringe to pass into the veins, and if there is a proper provision for the return of the fluid none of it will penetrate the oviducts. He has never seen any alarming symptoms after its use, and, on the contrary, praises it highly for its antiseptic effects and recommends it to his classes.

He also exhibited several glass tubes for intra-uterine irrigation. Each tube was about fifteen inches in length, closed at one end, the calibre being about two-thirds of an inch. The rounded end of the tube was perforated by a number of holes, for the escape of the fluid from the uterine cavity, which was to be injected through a soft-rubber catheter passing along the interior of the tube and through a terminal aperture. The glass tube could be made perfectly aseptic, while the rubber tube should be renewed each time it is used. He had employed such tubes, extemporaneously made, in his practice with satisfaction.

SCIENTIFIC PAPERS AND DISCUSSIONS.

Dr. JOHN C. REEVE, of Dayton, Ohio, read the first paper presented before the Society at the meeting on Tuesday morning, entitled

MOOT POINTS IN REGARD TO INVERSION OF THE UTERUS.

The progress of our knowledge with regard to inversion of the uterus, he said, had been very slow, chiefly, it was believed, on account of the rarity of its occurrence. Its infrequency may be judged from the fact that West did not meet with a single case in a total of one hundred and forty thousand labors; moreover, they happen mostly in the hands of midwives and unskilled observers, or of young practitioners, and under circumstances not favorable to careful observation. This also constitutes the stronger reason why their conditions have not been better studied. The accident was known to and described by the ancients. With regard to the etiology of inversion, some progress has recently been made, and it is now better understood than formerly. It was the custom to attribute the condition always to ignorance, and unskilled manipulations, of the midwife in delivering the placenta; now it is known that it may be due to muscular action of the uterus, without any aid on the part of the accoucheur whatever. Can inversion of the uterus occur entirely independently of pregnancy or of polypus in the nulliparous organ? It is generally supposed to be due to some change in the wall or the contents of the uterus. Pregnancy and polypus undoubtedly favor its development; but the question is, whether or not there are other conditions which may also be the cause. Hydrometra has been assigned as a predisposing cause by Courty, and one case apparently due to hydatids has been reported. It is admitted that with a healthy condition of the uterus this accident is impossible. Its occurrence independently of pregnancy is also accepted by Courty, Madame Boivin, and other distinguished authorities; by others, however, the inversion of the nulliparous uterus has been doubted, and it is denied by Matthews Duncan, West, and others. The chief objection of Matthews Duncan is that the wall of the uterus is too thick and muscular in virgins,—that it cannot be depressed or dimpled so as to admit of inversion. But this really begs the question, because it applies to the normal condition only; and the possibility of its occurrence, on the contrary, can be proved from the writings of Dr. Duncan himself. He has described changes which he has frequently encountered in the virgin uterus, where there has occurred a thinning of the walls as a result of pathological conditions where the walls were very much reduced. This condition—abnormal, it is true—is certainly favorable to the development of inversion, and it is not unfrequently found after operations for the removal of intra-uterine growths. He quoted three cases in support of this view. The first was reported by Baudelocque in 1790, the patient being fifteen years of age, which established the occurrence of inversion of the nulliparous organ. Case II. was reported by Beyer, in a woman aged forty-four years, and the third case was published recently by Gaillard Thomas. This case occurred in the practice of the late Dr. Willard Parker. The woman had had several children, and was supposed to have polypus; but upon removal of the tumor it was found to be the inverted uterus. The patient recovered.

Thus there are fair arguments in favor of inversion occurring in the absence of pregnancy and polypus, due to abnormal conditions of the nulliparous uterus.

The second question he propounded was with regard to the starting-point of the inversion: does it always begin at the fundus? This appears to be the generally accepted view; but may it not occur in a reverse way, from the cervix being relaxed and open and the organ gradually everting? Dr. Thomas claims that this has not been proved, and it

has been denied at a meeting of this Society by Dr. Taylor. A case was quoted from Klob, but upon referring to the original it seems that Klob referred to Tyler Smith.

He had not been able to find it in the published writings of Tyler Smith, but Dr. John H. Tate, of Ohio, who was a student and great admirer of Tyler Smith, had referred to it in a paper on this subject. and probably learned it from him. The process is very much like that which occurs in prolapse of the bowel,—a hollow organ rolling outward through its inferior outlet owing to pressure from above.

Dr. Tate, in his paper, communicated the notes of three cases which did not fit into any of the prevailing doctrines whatever. A case has also been recently met with by Dr. Araminta V. Scott, of Philadelphia, and reported by her, so that there seems to be sufficient evidence to support the proposition that inversion may begin at the cervix.

The third query he propounded was, Does puerperal inversion of the uterus occur except at the time of delivery or immediately afterwards? This question is an important one, because it affects the responsibility of the accoucheur. Suppose a woman has been attended through the usual course and has been dismissed as well, and some few days afterwards, while sitting up, perhaps straining at stool, she feels something give way, and an examination reveals an inverted uterus. The question is, did this begin at the time of labor, and was it overlooked by the attendant, or was it an after-occurrence? When inversion, partial or complete, occurs at the time of labor, the usual symptoms of inversion, hemorrhage and nervous shock, should be present to direct attention to the accident; and repeated hemorrhages within the first few days after confinement should suggest this possibility to a young physician, who is to blame if he neglect a vaginal examination, when the condition would at once be recognized. He recalled a case occurring twenty-five years ago in his own practice. Mrs. M. complained of pain in her side during her labor, which was rather a difficult one. After delivery, the uterus could be felt, as usual, above the pubes. On the fourth day she seemed to be doing well, on the tenth she was discharged. On the eighteenth day he was sent for on account of her having had some fresh hemorrhages; he found an inversion of the uterus, which he reduced three months after delivery. He regarded this as a case in which the inversion did not occur at the time of labor, but some time afterwards. The next case was reported by Dr. Delamater, from the practice of Dr. Sayles. It was a second labor. Apparently nothing unusual occurred, as the doctor was only called to remove the placenta, after doing which there was pretty free hemorrhage, which, as she had had hemorrhages before, did not excite apprehension. The uterus was in good position. For several days a catheter was used, but otherwise everything appeared to be normal until the tenth day, when the patient experienced an irresistible tendency to bear down, and, as the result, a tumor protruded from the vagina, which was recognized as the inverted uterus, and which was afterwards successfully reduced. In Case III. it was a twin labor; the patient was apparently well until the eighth day. On the next day she had a tumor like the preceding one, which was found to be an inverted uterus. Case IV., having been doing well, on the eighth day got out of bed to evacuate the bowels. A tumor protruded from the vagina, which was recognized as the uterus nine months afterwards and successfully reduced. In Case V. the inversion occurred on the fourth day; in Case VI., with the first labor inversion occurred, and again in the second and third labors; the uterus was in good position on the sixth day, but afterwards inversion occurred, which was subsequently reduced. Case VII. also had an inversion, occurring on the ninth day, the patient having been doing well up to this time. This was also successfully reduced.

With regard to the predisposing causes of inversion, it is observed that relaxation of the uterus after delivery is very common, and inversion under such circumstances is not only possible, but probable.

May it occur without giving rise to symptoms that would indicate that something was wrong? In most cases the shock, paleness, profuse hemorrhages, indicate to the friends that everything is not right, and in seventy-eight out of one hundred and twenty-eight cases a fatal termination occurred in a few hours. Two cases were quoted in which the patient seemed comfortable and there was no excessive bleeding. In one the uterus and its contents were forced out between the labia by one severe pain; the placenta was peeled off, the uterus restored to its position, ergot given to retain it in place, and the patient seemed to suffer no inconvenience.

The last difficulty to consider is one of diagnosis. Sessile polypi and inverted uterus might be confounded; the history of the two conditions is of no aid whatever in diagnosticating them, as they are so nearly alike. The only safe rule is to bear in mind that such a tumor may be an inverted uterus, and to use appropriate treatment after a careful examination.

DISCUSSION.

Dr. SCOTT, of California, said that, in a long experience, he had had only two cases of inversion of the uterus. One occurred during the early years of practice, coming on during labor in a young woman; it was reduced very speedily by manipulation. The second case occurred only last year. She was brought to him from Sacramento to San Francisco, having been under the care of a

homœopathic medical man. She reported that the child was not unusually large, and the labor was an ordinary one, but the doctor seemed in a great hurry to get away the placenta, which came away suddenly, with a gush of blood; during the next three weeks there were repeated hemorrhages. Her medical attendant recognized the case as one of inversion of the uterus, and tried, though unsuccessfully, to reduce it, and another irregular made the same diagnosis, but did not attempt its reduction. The remarkable feature in the case is that this patient had for the next seven months inversion of the uterus without hemorrhages, although she had pain in the back and most profuse leucorrhœa. In the eighth month she weaned her baby, and the hemorrhages immediately began again. The speaker examined her and restored the inversion in about twenty minutes by the usual method, by manipulation, first indenting one cornua, then the other, and gradually pressing the fundus through the cervix. In the process he could feel the muscular fibres yielding; some of them were torn. After the uterus had been restored, he examined it from day to day, and found that the os remained patulous; there was no tendency to contraction; the patient felt perfectly well. Iodine was applied for three weeks without much effect; then the menstrual period came on, followed by hemorrhage, continuing for ten days. An examination showed the uterus in place, but the cervix dilated as before. Applications were again made, but after the next period it was found that nothing had been gained. He then retrenched the calibre of the cervical canal by putting in some silver-wire sutures, which set up a cellulitis. The patient afterwards recovered, became pregnant, was delivered of a child, and he was called upon to operate for a rupture of the perineum. He reported it in order to call attention to the persistent patulous condition of the cervix.

Dr. William H. Byford said that the paper merits more notice than it could receive in a short discussion. The main points for discussion are the method of inversion of the uterus, its causes, and the times when it is likely to occur. With this accident he had not had much experience personally, although in consultation he had seen nine or ten cases, two or three being acute. Some years ago he had published a case, which occurred in 1870 in his own practice, of a very healthy young Jewish lady of this city, at her second confinement. The labor was not a marked one in any respect, and there were no untoward symptoms. He followed his usual custom after labor, and examined the uterus through the abdominal walls. He found it in good position, not altered in shape, and certainly not in position. There was no hemorrhage, and, in fact, no symptoms to indicate anything extraordinary. He could recall no circumstance afterwards during her confinement in bed to excite suspicion. Four or five weeks after her confinement he went to California, and was absent two months. Two or three weeks before his return, this patient had to call in another physician of this city to see her, who, upon examination, found an inverted uterus: there was complete inversion. He was astonished and perplexed to hear of this, and to think that he possibly might have overlooked a complete inversion. Now, it is noteworthy that, from the time of her labor to the time that this physician was called to attend her for a slight hemorrhage, there had been nothing to point to anything unusual. This patient had been nursing her child, also, until about two weeks before the occurrence of this accident. Owing to some sickness on the part of the child, the nursing was interrupted, and the hemorrhage began. It often is the case that pelvic disorders first make their appearance by symptoms after weaning the child.

In reply to a question, he said that such an occurrence had been the ground of a trial about twenty-five years ago. Dr. Fisher attended a case, and had in consultation with him Drs. Davis, McVicker, and others. The patient subsequently was found to have inversion of the uterus, which the husband attributed to unskilful attendance. Being an irascible man, he pursued Dr. Fisher, and tried to ruin his reputation, on account of his supposed neglect. Dr. Fisher sued him for damages for defamation of character, but did not gain the case. The affair ruined Dr. Fisher in Chicago.

Dr. Browne reported a case which was taken with hemorrhage on the ninth day after delivery, and inversion was discovered and put in place. In this case there was an ulcerated cervix, and probably the inversion had occurred from below. In cases where the uterus follows the placenta, the inversion is generally recognized at the time. We know how difficult it is to invert the uterus in cases of operation for removal of a sessile polypus; and in similar cases it seemed to him that the true explanation of the inversion is that it occurs from below.

Dr. Dunlap referred to a case of chronic inversion of the uterus which had come under his care, with a history of hemorrhages after labor, but no abnormality of the uterus was discovered upon repeated examinations until some months afterwards. Then the os was seen to be in a state of dilatation, and through it the uterus slowly descended until the fundus was in the vagina. The point of this case consists in the fact that at first the os was closed, and several months afterwards, with obstinate hemorrhage, there was found dilatation of the cervix and descent of the fundus. In this case inversion occurred at the fundus, and not at the neck or the os.

Dr. Sawyer had a fatal case of puerperal

inversion to report. There had been extreme dilatation of the uterus by dropsy of the amnion. The uterus was flabby, and walls deficient in thickness. The fundus was above the umbilicus, and there was some difficulty experienced in delivering the placenta, although, after evacuation of its contents, the uterus appeared as if it were normal, except that the fundus was a little higher in the abdomen. The husband was asked to place his hand over the uterus while the relator changed some clothing: now a gush of blood was noticed, and a drachm of ergot was given. Upon taking the place of the husband, it was found that the uterus had disappeared. The time in which the dimpling and inversion had occurred was not more than ten minutes altogether. During the efforts at reduction, the organ became hardened, probably from the ergot, so that it was impossible to reduce it; the patient became collapsed, and died in three hours. At the post-mortem, a condition was found which throws some light upon the method of production of inversion. The area of placental attachment was near the right cornua; the uterine wall was large, and much thicker here than elsewhere. There can be no doubt that this portion of the fundus fell in from the force of gravity, and he was prevented from reducing it by the uterus being ergotized, ergot having been given to stop hemorrhage that was threatening life.

Dr. H. P. C. Wilson said that he had been most interested in the length of time which inversion had occurred after labor. Inversion never occurs at any time after confinement without the physician getting the blame for it. He had seen but one case in his life of acute inversion after labor. It occurred in the hands of a very distinguished practitioner, and was brought to the reporter six months later. It was reduced without special trouble. It would seem that everything which produces relaxation of the uterus or favors subinvolution, or anything which prevents the uterus from resuming its normal condition, may produce inversion at any time, as long as this condition remains, whether one week or ten after labor. Anything which causes relaxation of the muscular walls under these circumstances, such as over-exertion, may cause inversion.

Dr. Howard had seen only three cases. He was called to a fourth, but had not been able to attend it. In the first case, the midwife had delivered the placenta by pulling upon the cord, producing complete inversion of the uterus. The temperature of the woman when he saw her shortly afterwards was 103° F., pulse 120. The organ was replaced by manipulation, and the patient did not have a bad symptom afterwards. The second case was a young mulatto woman, who had been exhausted by repeated hemorrhages and leucorrhœa, due to polypi, which being removed with the écraseur without loss of blood, the uterus was found completely inverted. The attachment of the polypi was seen to be to the fundus by pedicles. The third case was also one of complete inversion, supposed to be a prolapse. She refused operation. The last case was one which he had seen about a year ago. She was sixty years of age, and had complete inversion with a polypus. In consideration of her age, no recommendation was deemed necessary.

In a case where a polypus was attached by a long pedicle to the fundus, he had inverted the uterus by delivering the tumor with the forceps, and immediately restored it again. Now, if the uterus can be inverted by traction and reduced immediately afterwards, it seemed reasonable to him to believe that in a woman who has never borne children the uterus may be inverted by the constant traction of a polypus. In conclusion, he referred to the discussion on this subject before the International Medical Congress held in Philadelphia in September, 1876, when Dr. Washington L. Atlee handed around a specimen of a portion of an inverted fundus uteri, which he had removed with the écraseur under the idea that it was a polypus.

Dr. H. P. C. Wilson, of Baltimore, read a communication on

FOREIGN BODIES IN THE ABDOMEN AFTER LAPAROTOMY.

The possibility of allowing some of the instruments or a sponge to remain in the peritoneal cavity constitutes one of the great dangers of laparotomy; and this accident occurs more frequently than might be supposed from the records. The foreign body is sometimes discovered during life, sometimes only after death; sometimes it fails to be discovered at all. Unfortunately, most of the fatal cases have not been published, because they would do damage to the surgeon in the neighborhood in which he lives. Moreover, in a great many cases he is unable to obtain a post-mortem examination, and the diagnosis of septicæmia, peritonitis, etc., is usually considered sufficient, and it is never learned whether or not there may have been a sponge or a pair of forceps at the bottom of it.

Notwithstanding the difficulty of getting statistics of this accident, he had been able to get records of twenty-one cases, of which only five have been published; *i.e.*, more than two-thirds of the cases never come to light. Counting his own case, which he published to-day, there were six published. In five the foreign body was a sponge; in one, a pair of forceps. Four perished; two recovered, after timely removal of the sponge.

In his own case, when the wound was nearly closed, an assistant told him that a sponge was missing; but on counting them over, the nurse said that they were all accounted for. The patient made a good recovery, except that an abscess appeared on the anterior abdominal wall, which pointed

and discharged pieces of sponge six months later. The fact that the sponge had been thoroughly cleansed and asepticized probably saved the patient's life. He was entirely unable to account for its presence in the abdomen. In a case of Lawson Tait's, a bystander, becoming interested in the operation, assisted, and tore a sponge in two, and, without saying anything about it, he left the room before the sponges were counted. The number was correct, but the half-sponge left in the abdomen killed the woman. Spencer Wells reports a similar case, in which he was obliged to partially reopen the abdomen twelve hours later: he removed the sponge, and the woman did not seem any the worse for it. In another case, Spencer Wells, making some excuse, removed two stitches in order to find a pair of forceps, which were subsequently found rolled up in the mesentery. The patient got entirely well, and never found out anything about it. Carl Braun reports a case of a sponge, and Gustav Braun one in which a pair of forceps were allowed to remain.

In order to avoid such dangerous and disagreeable accidents, he urged that the number of sponges should be as limited as possible. The sponges should be selected on account of their strength, as well as their texture; they should not be too small, and should be whole, never cut or torn; they should not be used if old or friable. The instruments should also be large, because small ones might be overlooked. There should not be too many assistants: he would rather have one than three, and rather none at all than five. Both sponges and instruments should be entered upon a written list before the operation, and the surgeon should himself verify the count before closing the abdomen. The operator should do his own sponging during the operation.

DISCUSSION.

Dr. THOMAS said that the subject as presented by the lecturer was interesting, and the paper was characterized by frankness and an evident desire to avoid doing injury to patients. He thought, however, that the frequency of the accident had been overestimated. In his own experience of laparotomy, of between four and five hundred cases, there had been only one case that he could recall, and this he desired to mention as an addition to those in the paper, and as an illustration of the unaccountable manner in which this accident may occur. A patient in the Woman's Hospital, New York, suffering with cancer of the spleen and Bright's disease of the kidneys, had a tumor in the left side of the abdomen, and, although the case was a hopeless one, at the request of the patient's friends an exploratory incision was made. During the operation he did not have a sponge in his hand, and his assistant, Dr. Hunter, used only one sponge. The patient was under ether, as at that time he had not yet recognized the danger of giving ether in Bright's disease, which sometimes is followed by complete suppression of urine. It was so in this case: after the operation the patient did not secrete a drop of urine, but succumbed in a few hours. A small piece of sponge was found in the abdominal cavity, which had probably been broken off from the large sponge while it was being used in the peritoneum, and dropped inside.

Referring to the recommendations given in the paper, he said that he thought it impossible for the operator to do his own sponging, especially when there is a great deal of hemorrhage, or when he has to do some careful dissecting and differentiate the tissues, which would require sponging to keep the field of operation clear. He must, therefore, trust his assistants with the sponges; but he should see that nothing remains in the abdominal cavity. He has only three assistants, uses very few instruments, which are large, and his sponges have pieces of tape (five or six inches long) stitched to them to prevent their being overlooked. One assistant has charge of the instruments, and accounts for them all after the operation; a second assistant administers the anæsthetic; the third assists in the operation directly. The only way to prevent leaving instruments in the cavity is to use as few instruments as possible and let them be of large size. He had great dread of seeing Péan's forceps used, as they are generally allowed to remain temporarily in position, in order to check hemorrhage, but they might easily get lost. While such accidents do occur occasionally, he would not deny—in fact, he fully agreed with Dr. Wilson—that if all the cases were faithfully reported there would be a great many more than there are.

Dr. A. REEVES JACKSON said that having his attention directed to the subject he had found, upon inquiry, that there had been at least three unpublished cases in Chicago (two of sponges, one of forceps), and the fact discovered only after the death of the patients. He approved the sentiments and recommendations of the paper, which were very nearly his own rules. He thought that the case of Dr. Wilson fully demonstrated the value of antiseptic sponges.

Dr. DUNLAP had not had this accident occur, to his knowledge, in any patient of his. He uses very few instruments and does his own sponging. He thought Dr. Thomas's plan a good one. His own preference was for a very large blanket sponge, which he packed in over the intestines to keep them out of the way. He always has his patient in a half-recumbent posture during the operation, so that the fluids may gravitate to the posterior cul-de-sac. He has no dread in making an external incision large enough to permit him to explore the abdominal cavity. Having it open before his eye, it is impossible

to leave a sponge in unnoticed. The only danger is from Péan's forceps, and he prefers to apply a ligature at once to letting go of the forceps. He never passes a vessel until the bleeding is stopped, and he does not close the wound until the cavity is perfectly dry. He recommends large incisions, and said that in all his laparotomies he had never failed in obtaining union in three days' time.

Dr. HOWARD said that he was struck with the manner of counting the sponges in the Good Samaritan Hospital in London. Two women have charge of the sponges,—say fifteen in all. After the operation, one woman picks up the sponges one by one and counts them aloud, handing them to the other nurse, who also counts them aloud as she receives them, which prevents any mistake in counting. While in London he learned of a case of a young woman, nineteen years of age, who, after ovariotomy, complained of so much pain that a young surgeon in the hospital opened the wound and removed a sponge, and the patient recovered. Another distinguished operator opened the abdomen of a patient on account of pain, which he feared might be due to a sponge, but he could not find any: this patient died. With regard to Dr. Thomas's remarks about the danger of ether in Bright's disease, he thought that this was also the case with chloroform, and that deaths under such circumstances had been published. He had himself a case of a young colored woman who died of cardiac paralysis after the inhalation of less than thirty minims of chloroform in a Junkin's inhaler: after death the kidneys were found diseased.

Dr. THOMAS said that the case was not analogous. He had referred to suppression of urine after the use of ether, which did not occur with the chloroform.

Dr. ENGELMANN reported a case of laparotomy for fibro-cystic tumor of the ovary, where a sponge was left in the abdomen by a visitor who usurped the place of the regular assistant, and who afterwards corrected the assistant, who reported a sponge missing, by the assertion that it was all right, and must have been thrown out with some waste water. As no sponge could be detected in the pelvis, the wound was closed. The patient did well for two days, and then sank, with peculiar symptoms of dementia, or melancholia; she did not complain of pain in the abdomen. At the post-mortem, a small sponge was found lying between the stomach and transverse colon, mainly on the right side. There had been no inflammation around the sponge, which was perfectly pure and clean; there was a slight injection of the small vessels in the immediate neighborhood of the sponge. This case is of interest because the list is so small. It occurred because of the interference of a guest, and the deference due him as a distinguished surgeon prevented a remonstrance, and the manner in which it happened was this: in order to stop rather free bleeding, the visitor packed several sponges in succession into the abdomen in order to check it: one of these sponges was left.

Dr. MUNDÉ endorsed the caution with regard to old and friable sponge. His own rule was not to use sponges that have been long kept (antiseptic fluids usually make the sponge brittle), nor would he use one which has been cut or torn. He considered it advisable in the last steps of the operation to have as many sponge-holders as sponges, to use in taking the fluids from Douglas's cul-de-sac.

Dr. BAKER had expected to hear discussed in the paper another class of foreign bodies in the abdomen,—viz., sutures and ligatures. He had met with several cases in which ligatures, after giving considerable trouble to the patient, had gradually worked their way to the surface.

Dr. WILSON closed the discussion by approving most of the suggestions, and stated that the cases must be more frequent than some supposed, for, since writing his paper, he had learned of seven more cases.

Dr. C. D. PALMER, of Cincinnati, read a paper entitled

ABDOMINAL SECTION: ITS VALUE AND RANGE OF APPLICATION AS A MEANS OF DIAGNOSIS AND TREATMENT.

After referring to the value of diagnosis in medicine, he spoke of its especial importance in pelvic and abdominal disorders in women, and cited instances where circumstances prevent a positive conclusion from being drawn, —*i.e.*, some cases of ovarian cyst, effusion in the Fallopian tubes, cancer, and other growths which may be complicated by ascites. Sarcoma of the mesentery is likely to be taken for ovarian cysts. Neither the external character of the tumor, its relation to the intestines, nor functional disturbances of the kidney or other organs can be relied upon to establish the diagnosis. Renal tumors or floating kidney may have the intestines above them, and may be as movable as ovarian growths. Extra-uterine pregnancy also has simulated ovarian tumor. Although there is so much difficulty in diagnosis, it must not be inferred that many mistakes are being made in this department; on the contrary, it is surprising that they are so rare. Ovarian diagnosis is steadily increasing in accuracy. Spencer Wells has said that ovarian diagnosis has reached a degree of perfection as great as any other department of surgery.

Great stress has been laid upon tapping in the diagnosis of abdominal effusions; but, while some insist on its value, others never perform it. Probably the safe ground lies between the two extremes: it may clear up the diagnosis, but, on the other hand, how

many promising cases ready for ovariotomy have been spoiled by injudicious tapping! Spencer Wells estimated that tapping increased the mortality after ovariotomy two per cent. It is an operation of no small risk, in his estimation, and should be omitted, for the diagnosis can be made without it by means involving less risk. Schilling says that tapping is a crime. Stone never taps. Lawson Tait insists that it should never be done for diagnosis. He concluded (1) that tapping in the large proportion of cases is unnecessary, and is superfluous for the purpose of diagnosis; (2) that it is attended by such risk and dangers in its remote effect as to limit its use to a minimum. Spencer Wells limits it to the case of parovarian cyst; but the simplicity of the operation is likely to lead us to underrate its danger. The evidence afforded by the chemical, microscopical, and physical examination is only presumptive, and not positive.

With regard to opening the abdomen, which is generally regarded as a serious operation, he believed its danger was in proportion to the amount of handling to which the viscera were exposed, and the size of the external wound. After referring to the favorable reports of Spencer Wells, Dr. Byrd, and Dr. C. C. Lee (the last-named of whom had seen five cases in which the operation of laparotomy had been begun, and abandoned after opening the abdomen, all of the five recovering), he said that his own experience had been limited to five cases of exploratory incision where malignant disease was suspected and found. In four cases death occurred in from four to thirty days; the other is still living, sixteen months after operation. In cases of malignant disease with very little vitality, the shock of opening the abdomen very often will prove fatal; but in other cases exploratory section may be practised with as good results as tapping. He repeated Lawson Tait's warning against turning an exploratory incision into an incomplete operation, for the mortality in abandoned operation is very much greater than in simple section.

In a certain sense every abdominal section is diagnostic, because no one can tell positively, until the abdomen is opened, what the character of the tumor may be or what complications may exist affecting the question of operation. It is no reproach to a surgeon that he suggests an exploratory incision in order to complete his diagnosis; but it should not be resorted to except in cases where a surgical procedure is likely to be called for, and this contingency is to be provided for in case the abdomen is opened. Early interference gives the best results, and is the order of the day. The incision should be at first small, and may be afterwards enlarged according to the necessities of the case: by opening the abdomen the operator learns the character of the growth, whether malignant or not, its site and attachments, and is able to decide the question whether removal is possible, and, if so, whether it will prolong life. As the rule, no operation should be performed in malignant disease.

There are many conditions which can be relieved by the operation in which exploratory incision for diagnosis is not required:

1. For the detection of simple ovarian tumors; but such tumors are not always uncomplicated, and exploratory incision may be of service where it leads to early operation.

2. For the diagnosis of some interstitial and extra-uterine fibroids; but where life is threatened and surgical interference is needed, the section may be made to verify the diagnosis and enable the surgeon to decide between oöphorectomy and hysterectomy.

3. In certain cases of acute and chronic peritonitis, where the patient is threatened with septicæmia. If the abdomen can be opened, cleansed, and drained, the patient is in a fair way for recovery.

4. In certain obstructions occurring in the intestinal tract, just how soon and how far it is permissible to interfere surgically in such cases is yet undecided; but laparotomy has more than once been of service in saving life.

5. Some cases of chronic pelvic abscess are susceptible of relief by this means. A very large proportion of these cases result from hæmatocele. Many of these cases recover by spontaneous evacuation through the bowel or bladder. Tapping is the best method of treating such collections; but where the abscess is discharging through several tortuous channels, free opening, cleansing, and drainage are advisable.

6. In extra-uterine gestation, laparotomy should be practised early if the fœtus cannot be destroyed by electricity. When the fœtus is fully developed, it becomes a necessity.

DISCUSSION.

Dr. ENGELMANN said that the exploratory incision had been too little used in this country for diagnostic purposes. He would not regard it as a means of ordinary diagnosis, as he would bi-manual manipulation; but where the diagnosis is doubtful, the term exploratory incision will often aid in getting out of it if the case is not a suitable one for operation. He does not regard it as being as dangerous as tapping. He recalled three cases in which he had performed exploratory incision, all of whom got well. The first was one of uterine cancer, which seemed favorable for hysterectomy; but after opening the abdomen the disease was found in the neighboring structures, and the operation was not performed. A second was of similar character; and in the third the malignant disease seemed generally diffused.

Dr. MUNDÉ said that exploratory incision, not only in suspected ovarian diseases, but in abdominal disorders, had not been as much

*

resorted to as it should have been. At the commencement of the operation the majority of ovariotomists make a large incision, with the expectation of going right on with it, and with the feeling that, having begun the operation, they do not like to back out of it; they go on to finish the operation, even if it also finishes the patient. He agreed with the lecturer that the exploratory incision is rather a safe procedure, and not so dangerous as tapping. He believed that tapping was responsible for twenty-five per cent. of the mortality after ovariotomy, and the risk is greater than from the ovariotomy itself. He has now under treatment a large uterine myoma, for which he proposes, within a month, to make an exploratory incision, and afterwards determine whether to remove the uterine appendages or perform hysterectomy. In a case of pelvic abscess he preferred to aspirate, and, finding pus, to make a free incision in the roof of the vagina, tie any bleeding vessels, pack the cavity, and the patient usually gets well. He only differed from the speaker in calling this an exploratory incision, agreeing with him as to after-treatment.

Dr. WILSON regarded every laparotomy as an exploratory incision: he never knows exactly what he has until he opens the abdomen. It is not so dangerous as tapping. In a case of amniotic dropsy with great abdominal distention, although he was aware of the existence of pregnancy, yet the effusion was so great that he did not know whether it might not be ovarian tumor or ascitic fluid. After deliberating whether to open the abdomen or to put in a trocar, he decided to make an exploratory incision, and found a very large uterus, the walls not being any thicker than an ordinary cyst of the ovary. If a trocar had been used, it would have gone immediately into the uterus. As it was, he closed the wound, dilated the mouth of the uterus, ruptured the membranes, and gave exit to several gallons of fluid, delivered twins, and the woman got well. In closing, he repeated that every laparotomy is necessarily an exploratory incision.

Dr. MAURY said that he had had two abdominal sections for exploration. The first was supposed to be a multilocular ovarian cyst, and there seemed no doubt about the diagnosis, but the incision showed it to be a tumor of the mesentery. The wound was closed, and the patient recovered and lived for a year afterwards. In the other case, a large myoma filled the entire pelvic cavity. The question of removing the ovaries was considered. Upon opening the abdominal cavity it was found to be impossible to remove the ovaries. The operation was given up, and this patient also recovered.

Dr. JACKSON said that the paper had a wider range than the discussion. He would like to hear the experience of the Fellows as to the value of abdominal section for pelvic abscess.

Dr. DUNLAP reported a case of a man, a physician, who came under his care, suffering with commencing psoas abscess. An exploratory incision in the median line, below the umbilicus, revealed the abscess, which was opened and washed out. The patient recovered.

Dr. SCOTT also recalled a case of pelvic abscess, in which the operation was delayed by the refusal of the patient. Finally the abdomen was opened, and it was found that a communication had been formed between the abscess and the large intestine. The result of the operation was very favorable. Obstinate vomiting at once ceased, the condition steadily improved, and the opening in the bowel probably closed, as the patient got entirely well. In another case, drainage by the vagina failed to empty the collection, and abdominal incision was resorted to, and the original cause of the trouble was found to have been a suppurating salpingitis, the cellulitis having been secondary. The patient, before the operation, had been suffering with septicæmia, and died two days later. If the abdominal incision had been made early for diagnostic purposes, the patient might have recovered.

Dr. PALMER closed the discussion by repeating some of the points in his paper. With regard to chronic pelvic abscess he said that simple exploratory incision is a matter of duty on the part of the attendant, especially when the track is long and tortuous, and when it cannot be reached from below. In conclusion, he recommended the more frequent performance of laparotomy, both as a means of diagnosis and for the purpose of opening methods of treatment which otherwise would be impossible. He would not recommend it in marked malignant cases when the vital powers are low.

Dr. ENGELMANN, by permission, stated that in a case of malignant disease operated upon by him the union was by first intention, and the patient rapidly recovered from it.

Dr. PALMER repeated that in four cases under his care of malignant disease the patients died in from four to thirty days after the operation.

Dr. PAUL F. MUNDÉ, of New York, read a paper on

CERVICAL FIBROIDS AS A CAUSE OF DYSTOCIA, AND THEIR REMOVAL BY VAGINAL ENUCLEATION.

The usual site of fibroid growths is in the uterus rather than in the cervix; but they do occur in this situation, and, like other fibroids, they grow rapidly during pregnancy. They may grow so large as to fill the upper portion of the pelvic canal and make delivery extremely difficult; and, when so large, they are apt to be partly corporal and partly cervical. The tumor may descend in front of the head of the fœtus, and may be so contused as to

slough off, or its size may be so reduced by hemorrhage and pressure as to allow it to retire above the brim of the pelvis, and delivery may go on. If the fibroid has a long pedicle, it is easily removed, but the case is more difficult when it is sessile; and it was of this condition that he wished especially to speak. When the sessile fibroid is large, and labor has begun, two plans of treatment are possible: 1, to excise the tumor piecemeal, or, 2, perform Cæsarean section; but the results of this are so bad that the former is preferable. Out of thirty cases, there were twenty-four cases of maternal death, and sixteen of the child. Schroeder showed a mortality of sixteen per cent. The dilatability of the parts at the time of labor is an additional argument in favor of enucleation, and renders the operation more successful than under ordinary circumstances. Dr. Thomas operated upon a woman by Cæsarean section under these circumstances, and the patient died. Afterwards, in speaking of the case, he said that in a similar one he would now try enucleation with the serrated spoon. Where the child is not living or viable, vaginal enucleation would always be preferred. He reported the following case. Mrs. F. F., 38 years of age, married, had her last child a year ago. She had had hemorrhages before delivery (supposed placenta prævia), and bled for five or six months afterwards, and at intervals ever since. She was brought into the hospital with the curious diagnosis of "elephantiasis ossis uteri," whatever that might be. A large fibroid growth was found filling the upper part of the vagina, and the tumor extended up to the diaphragm. Pregnancy was detected, but the tumor so completely blocked up the pelvis that the finger could not be passed beyond it, or between it and the promontory of the sacrum. He did not interfere much with it, for fear of inducing premature labor, which had reached the sixth month. After checking hemorrhage with astringents, the question was whether to operate at once or to delay. Two courses were open: first, to wait, controlling the hemorrhage as much as possible, until labor began, and then to enucleate and deliver, or, if not, to remove the child by Cæsarean section, and finish with Porri's operation, or to perform intra-abdominal enucleation, with abdominal section, by the method of Bryson. In the latter case the chances of the mother would be extremely poor, the mortality being about eighty per cent. Moreover, while waiting, the tumor would have time for still further development, and possibly make Cæsarean section absolutely necessary.

The second plan was to wait only a couple of weeks, and then remove the tumor without interfering with the pregnancy, if possible.

A case of Schroeder's, reported by Loman, his assistant, was almost identical with this one. He performed the operation towards the close of pregnancy, without interfering with it. The success of this case of Schroeder confirmed the lecturer in his intention to operate at once, since the delay until full term would be extremely hazardous.

The operation was accordingly performed, traction being steadily kept up on the mass by two volsella forceps, bringing it down as it was enucleated by the serrated spoon; finally, as the forceps pulled out, he hooked his fingers in the mass and delivered it. The amount of bleeding was slight, and no hemorrhages occurred subsequently. Labor came on shortly afterwards, and he removed the fœtus and placenta and packed the wound with iodoform gauze. The patient did not rally well from the ether, but finally revived after artificial respiration and nitrite of amyl inhalations. There was a temporary rise in temperature for two days, but the patient subsequently did well. The wound was cleansed and again packed on the second and third day afternoon, and less frequently afterwards; it was entirely closed at the end of three weeks, and several weeks later only a slight thickening of the posterior lip of the cervix was present. The tumor, which was presented to the Society, measured twenty inches in circumference, and its principal diameters were eight by six by two and a half inches: it weighed fifteen hundred grammes, or about three pounds.

After a reference to cases published by Playfair, Braxton Hicks, and Loman, he concluded that this case was the largest growth of the kind yet recorded.

So far as can be judged from the description, the size of the tumor in this case is double that of any of the eight cases collected by Loman, and is approached only by Schroeder's, which was six inches long to eight in this one.

To collect the results of these nine cases (only eight of which were available, since Langenbeck's had not been decided at the time of reporting): we find that the mothers all recovered without difficulty. Of the children, three were premature and not viable; one was extracted dead by version, one was perforated before the tumor was enucleated, one was delivered by the forceps asphyxiated (whether resuscitated or not is not stated, but it probably was, or it would have been reported as dead), and two were born alive after enucleation of the tumor,—one by the forceps, the other spontaneously. Thus, of five children, which only can be included in this estimate because they only were viable, three were born alive, or could probably have been born alive if the tumor had been enucleated before perforation was thought necessary, and one died during extraction after version, an operation known to be frequently fatal to the child under any circumstances. Thus, all the children of the cases in which the proper treatment of enucleation was adopted, before attempts at delivery were made, were saved.

Truly, not a bad showing; but how different from twenty-four dead mothers and sixteen dead children out of thirty Cæsarean sections for the same condition!

That the loose connection of these tumors to their envelope during gestation greatly facilitates their enucleation is obvious, and the softness of the mass, also peculiar to pregnancy, allows tumors of even considerable size to be elongated and attenuated by traction, and thus removed through the pelvic outlet, which in the non-parturient condition would be entirely too bulky for that orifice without mutilation; and fortunate it is that these favorable conditions exist at that time. The dangers to the mother from septic causes through the large raw tumor-cavity did not seem as great as we might expect, since in the case he had reported there was only a temporary rise in temperature. He said, in conclusion, that "it is to be hoped that in future, when a fibroid, no matter how large, is found obstructing delivery, the attempt will always be made to enucleate it, either whole or in part, through the vagina, before endeavoring to drag the child past the tumor with the forceps, or performing craniotomy or version, or, worse than all, sacrificing the mother and possibly the child by Cæsarean section."

In the discussion on this interesting paper, in which Drs. JENKS, WILSON, BYFORD, DUNLAP, VAN DE WARKER, and REAMY engaged, the rarity of this complication of labor was dwelt upon, and a general approval of Dr. Mundé's course was expressed.

Dr. T. GAILLARD THOMAS exhibited a form of apparatus which possessed historical interest. It was a jointed steel girdle, covered with velvet and fastened with a lock. The special feature of the apparatus consisted of a steel perineal band, having apertures opposite the vulvar and anal orifices when in position; these apertures being surrounded by sawteeth. This apparatus (similar to that exhibited at the Hôtel de Cluny at Paris) was found in several pieces in an old trunk received among a lot of effects from an old French estate by a resident of Long Island, who had presented it to Dr. Thomas, who had had it restored and prepared for exhibition to this Society.

Dr. THOMAS then proceeded to read his paper on

A FURTHER REPORT UPON EXTRA-UTERINE PREGNANCY, EMBODYING SIX CASES.

Since reporting twenty-one cases to this Society in 1882, he had seen six more, which he wished to add to the statistics. Most of these cases had been seen in consultation, which would account for the large number in his individual experience. On account of the liability to rupture of the sac towards the fourth month, he advocated early diagnosis and early treatment.

The experiments of Leopold upon artificially-produced extra-uterine fœtation in rabbits and its results he considered as of great interest in this connection. Leopold concluded that rupture of the sac is a common result in extra-uterine pregnancy, and that the dead embryo is usually encapsulated and remains as a foreign body. The inference that recovery in the human race, after similar rupture, may take place, was one that Dr. Thomas fully endorsed. In case of active hemorrhage, the operation of opening the abdomen and the application of ligatures to the bleeding points was advocated twenty years ago by Dr. Stephen Rogers, of New York; but he had no actual experience in such an emergency. Lawson Tait had reported, in the *British Medical Journal*, five cases operated upon in January, 1883, four of which recovered, one died. His own experience had proved that this treatment was entirely justifiable. Dr. Charles K. Briddon, of New York, following Tait, had operated in October, 1883. The history of this case is included in the series of this paper.

Case I.—Mrs. F., 27 years old. Four weeks after cessation of menstruation she received a shock in stepping from a street-car; she had an attack of pelvic peritonitis, and was sick for several months, during which time the abdominal tumor steadily enlarged. Her progress was steadily towards death. An examination failed to establish an accurate diagnosis. Aspiration was performed, and about four ounces of straw-colored fluid were obtained. Subsequently her sufferings became agonizing, and, except when relieved by morphia, she had constant vomiting. Death occurred twelve hours later. At the post-mortem the uterus was found enlarged and pushed forward. There was general peritonitis. A fœtus of four months was found in Douglas's cul-de-sac. Had an accurate diagnosis been possible, laparotomy would still have been fatal. This was the third case in which he had performed aspiration in the early months of pregnancy, and all three proved fatal.

Case II.—Mrs. G., 32 years of age, had had three children. Menses had stopped for nineteen days. The patient was in an unfavorable condition for operation, and, as there were some doubts as to the diagnosis, a week later it was decided to try electricity. The battery was used for five successive days, one pole in the rectum, the other upon the abdomen, using a strong faradic current. The tumor became smaller, harder, and finally disappeared. This was a case of most desperate character, and he had no doubt that had any other course been pursued she would have died.

Case III.—Mrs. H. had had three miscarriages, she also had a suspected extra-uterine pregnancy, and was treated by the faradic current from a Kidder battery, and, this not proving sufficient, the continuous current was used from twenty cells for several days. She

also made a good recovery. Had he not been successful in destroying the fœtus, he would have performed laparotomy.

Case IV.—An Irish lady, four months pregnant; examination showed an ectopic gestation, the tumor tying behind the uterus. The same treatment was instituted. The patient entirely recovered.

Case V.—Mrs. F., 28 years of age, mother of five children. This was the case of rupture of the Fallopian tube in which Dr. Bridon performed laparotomy. The patient rallied, but died soon after operation.

Case VI.—Mrs. X., 23 years of age, married six years; mother of one child four years old. In this case pregnancy had advanced to the ninth month. She sent for her doctor (Dr. Jewett) with all the symptoms of labor. The os did not dilate as the result of the pains, and an examination showed that the uterus was empty. Dr. Thorne was called to see the case, and diagnosticated ectopic pregnancy, but saw no reason for operating, as the child was dead, and he had had so much trouble with the placenta in his other case. The rule should be not to operate because the fœtus is in the abdomen, but because the fœtus is giving trouble. He preferred not to operate at full term, but to wait until the placenta shrivels, unless the child is known to be alive. This patient was afterwards taken to the Woman's Hospital, and Cæsarean section performed. The placenta was the largest he had ever seen, and weighed four pounds. The fœtus weighed sixteen pounds. The sac was attached to the ascending, transverse, and descending colon. Fearing to leave it to cause septicæmia, he made a continuous cobbler's stitch about an inch from the intestine, and removed the remainder of the placenta: he then brought the remnants of the sac down to the lower angle of the wound, and fastened it there, "marsupializing the woman," as Dr. Pallen says. The antiseptic procedure, except the spray, was adopted. She subsequently entirely recovered.

In three other cases he had adopted this expedient of fastening the placenta in the wound and allowing it to slough away. After the fourth month he advises waiting for indications for operating; before that period, although the great triumphs of abdominal surgery might lead us to suppose that laparotomy is the preferable method, he advised the trial of electricity, an infanticide agent of great value, which in the early months of extra-uterine gestation should always be preferred to the dangerous expedient of laparotomy.

Dr. R. B. Maury, of Memphis, read the notes of

A CASE OF TUBAL PREGNANCY WITH RUPTURE OF THE SAC.

The patient had been delivered of a child three years before, when there was no evidence of abdominal or ovarian disease. Her menses were profuse and irregular; she had pains in the hypogastrium at intervals, and when he was called in she had an apparent attack of collapse, with symptoms of intra-peritoneal hæmatocele. She received usual treatment for shock, but without bringing on reaction; the patient was thought to be dying. Upon examination later in the day, the uterus was found enlarged, and just above the pubes, and behind it a small tumor could be felt through the abdominal wall, rising half-way to the umbilicus: it could not be reached by the finger in the vagina. The diagnosis was tubal pregnancy. Afterwards symptoms of peritonitis appeared; on the sixth day she had a chill, temperature 103°, pulse 150; on the seventh, temperature was again 103°; but on the next day it fell to normal, and did not rise again. Subsequently the tumor became progressively smaller. Six months afterwards she had a uterus as movable as in health, and behind it a small hard tumor. Hemorrhage had entirely ceased. There had been no deciduous membrane. With regard to etiology, he only submitted one observation, —that the husband had a stricture of the urethra, and had had urethritis several times in the preceding two years.

With reference to the question of laparotomy in this case, recognizing the rupture, the question of operation was discussed, and it was decided not to operate until she got over the shock. After waiting for several days, he had written to Dr. Thomas, who advised him to wait for symptoms, and, if pelvic peritonitis appeared, to operate. The result showed the wisdom of this course. It would seem to be the better course for surgeons in such cases to postpone operation until the shock of the rupture has passed away.

In the rather desultory discussion which followed, Drs. Mundé, Harvey, Palmer, Wilson, Howard, and Baker reported other cases, and expressed views substantially in accord with those of the lecturer.

Dr. Paul F. Mundé, of New York, read a paper entitled

THE PROPER LIMITATION OF THE OPERATION OF COMPLETE VAGINAL HYSTERECTOMY FOR MALIGNANT DISEASE.

A strong and apparently convincing paper upon this subject was read at the last meeting of the Society, which declared that, both as regards the immediate fatality of the operation itself and the speedy recurrence of the disease, the operation was unjustifiable. In this verdict the Society apparently concurred, with the exception of two members. To the author this absolute condemnation of the total removal of the cancerous uterus seemed hasty, premature, and based upon insufficient clinical experience. Had the condemnation been restricted to the method of Freund of removal by abdominal

section, he would have heartily endorsed it, as it had developed a mortality of sixty-six per cent., and in the few cases of recovery the speedy recurrence of the disease took place almost without exception. This operation has been abandoned by Freund, or at least restricted to exceptionally favorable cases of undoubted limitation of the disease to the body of the uterus, with unusually thin walls and lax ligaments. This operation he had not personally performed, but had seen several cases in the hands of several eminent operators, who, after persistent efforts, either failed to remove the uterus, or in doing so completely exhausted the patient, the result in either case being speedy death from shock or hemorrhage. But the Society apparently condemned all operations for the removal of the cancerous uterus, apparently overlooking the excellent results of the removal of the organ through the vagina. It is due to the many experienced surgeons and conscientious operators who hold a different opinion, and to the interest of progressive surgery, to enter a respectful protest against the wholesale condemnation, at least so far as this vaginal operation is concerned.

As early as 1876 (two years before Czerny, of Heidelberg, revived the old, long-forgotten operation of Sauter, of Constance, who was the first to devise this method and carry it out successfully), the author's attention had been directed to the operation, and before the New York Obstetrical Society (October 17, 1876) he had made this suggestion, during the discussion of a fatal case of the abdominal operation for hysterectomy. While at Wurzburg in 1868, he had seen a reprint of an old graduation-thesis presented to the University of Göttingen, written in 1827 by Von Siebold, on the "Extirpation of the Cancerous Uterus." After reviewing the various methods of Sauter, the elder Langenbeck, and others, he said that his personal investigations on the cadaver had demonstrated the impossibility of detaching the peritoneum from the non-puerperal uterus above the level of the internal os. A perusal of Schroeder's operation of wedge-shaped excision up to the internal os and of vaginal extirpation, together with Dr. Jackson's paper, decided him to seize the next favorable opportunity to perform the latter operation.

Case I.—E. M., 43 years, ten children, two abortions, came, in October, 1883, to his service at the New York Polyclinic for menorrhagia existing six months. Last child born nine years before. Cancer of cervix was found, extending upwards, but limits could not be ascertained. Uterus was freely movable, vagina capacious, parametrium apparently free of disease. No enlarged glands or induration of any kind in the pelvic cellular tissue. Vagina healthy, general health still fair. On October 10 the operation was performed. Sims's position; uterus drawn down with double volsella forceps; with a knife he first made a semicircular incision through the anterior fornix vaginæ, pushed up the bladder with the fingers, then completed the circuit of cervix by posterior incision, detaching the vagina very easily with the fingers, except at the side where the vessels enter and leave and the folds of the broad ligaments join each other. Two fingers of the left hand were entered in Douglas's pouch, to the right border of the uterus, and the peritoneum was then pushed out and severed with closed scissor-points; the peritoneum was then readily torn, so as to leave the uterus free except the attachment of the broad ligaments. Seizing the fundus with a tenaculum through the posterior opening, with extra-abdominal pressure the uterus was retroverted, and after considerable difficulty, owing to the large size of the uterus, it was drawn through the posterior incision. Each broad ligament was now tied in three sections with No. 2, braided, carbolized silk, and divided with scissors. The application of the ligatures was quite difficult, but no blood was lost from the ligaments, and not more than a few ounces in all. The ovaries were readily removed with the tubes. The patient's condition was good. The wound in vaginal vault was closed with silk sutures, the peritoneum not being occluded. A rubber drainage-tube was introduced, and the vagina packed with iodoform gauze. There was no shock. On third day the tampon was removed and vagina irrigated; on seventh day drainage-tube was removed. Patient left bed on twelfth day, and on the thirteenth all but three of the ligatures came away; the stitches were removed on the sixteenth, when the wound was practically closed. Patient recovered from the operation. There was no return of the disease for nine months, when it reappeared in the cicatrix. No further operation is contemplated. The patient's general health is still good.

In Case II. the operation was a difficult one, the disease having extended to the surrounding tissues. The patient did not react from the shock, but perished a few hours later. In a similar case he would not again perform the operation, nor would he consider it advisable.

Admitting the truth of Dr. Jackson's first conclusion concerning the difficulty of early diagnosis of uterine cancer, he claimed, however, that our facilities, both as regards the greater readiness of the female sex to submit to examinations when the significance of certain symptoms is made clear to them, and as regards the early recognition of cancerous degeneration, will doubtless improve with every year. He said that it will be granted that the number of cases in which vaginal hysterectomy for cancer is indicated as justifiable and offers fair chances of recovery will always be small. Out of 812 cases of uterine cancer seen by Schroeder or his assistants,

only in 34 was colpo-hysterectomy performed. Marter reports 52 hysterectomies; Olshausen, 32; and out of over 160 cases of uterine cancer which he had seen, he found only 2 cases which seemed to him to permit the radical operation. So far as the first-named operators are concerned, their indications have been, by their own statement, considerably restricted since they began to operate.

Secondly. Dr. Jackson states that, the diagnosis once established, there is no hope for a radical cure. This is refuted by Carl Braun's statistics for various operations, chiefly the galvano-caustic amputation of cervix. Paulet reports 136 operations of this character, 10 of which proved fatal; and of the 126 patients who recovered, 31, or 25 per cent., remained well after two years. Schroeder reports 129 cases operated on during the last eight years: 28 cases, or $21\frac{8}{10}$ per cent., remained well after two years. He frankly states that in 4 of these cases the disease returned as late as from two and a half to three and a half years, but 24 remained well after this period,—certainly an excellent result in this fatal disease.

The operation compares favorably with that for cancer of other organs. Surely no one will doubt the correctness of the diagnosis in the hands of such an experienced gynæcologist as Carl Braun. A disease in which 144 of the patients remain well after two years cannot be said to be incurable by operative measures.

Tables were then shown in reply to the statement that the operation is a highly dangerous one and affords to those who recover no hope of radical cure, which show that out of 82 operations there were recoveries in 48, and 32 remained well after two years. The comparatively few cases which have been under observation for two years or longer after the operation may appear strange; but it is because the operation is so recent that the few operators have had no opportunity of following up their cases, or, if they had, they have not yet reported them.

The result of 39.5 per cent. compares very favorably with Paulik's cases of removal of cancer of the cervix (only 25.0), or of Schroeder (21.8), after different methods of operating.

The lines of the operation certainly need to be more strictly drawn. The presence of enlarged glands or infiltrations of any kind in the parametrium (vaginal wall or pelvic cellular tissue), the fixation of the uterus, even to the slightest degree of exudation,—these conditions should absolutely contra-indicate hysterectomy. A rectal examination with the finger will prove of great value in determining these points.

He said that in the discussion at the Berlin Obstetrical Society (May 23, 1884), Löhlein, Ruge, Olshausen, Hofmeier, and Marter had spoken in favor of this operation when performed in selected cases.

Thirdly. As regards the danger of the operation itself, it has been exaggerated by Dr. Jackson. Ovariotomy is also dangerous, but it is justifiable. So are nephrectomy and other major operations. A table was here introduced to show the mortality directly following the operation of vaginal hysterectomy for cancer: 235 cases and 52 deaths in Europe; 21 cases and 10 deaths in America; making 256 cases, with 62 deaths, or 24.6 per cent. This disproves Dr. Jackson's statement as to immediate danger of operation.

The two main questions to be decided are really,—

1. Can vaginal hysterectomy for uterine cancer be performed without so great a loss of life as to render it unjustifiable? and,

2. Can we hope to secure by it complete immunity from a return of the disease, or at least so much relief from suffering for several years as to compensate the patient for the risk she incurs of losing her life by the operation?

To each of these he returned an affirmative answer, and then proceeded to consider the details of the operation. In conclusion, he said that, inasmuch as vaginal hysterectomy is an operation based on sound surgical principles, the object of which is to save and prolong life, and not to shorten it, and as the indications for results and justifiability of operation are not a matter of sentiment or theoretical reasoning, but of solid facts and figures, the operation is one which should not be absolutely rejected, but increasing experience will show its usefulness in its limited field. Finally, he reviewed the minutiæ of the operative procedure for vaginal hysterectomy, the success of which would be favored by early operation, before the general health is seriously impaired, and before the disease has extended far into the uterus. Where surrounding tissues or organs are known to be involved, the operation is not justifiable.

DISCUSSION.

This paper gave rise to a spirited discussion, shared by Drs. REAMY, JACKSON, VAN DE WARKER, ENGELMANN, PALMER, BAKER, SCOTT, FENGER, and MUNDÉ. The different speakers varied radically in their recommendations, and differed in opinion upon the utility of any operation whatever in cases of uterine cancer. Hysterectomy was considered an heroic remedy, whose limits of usefulness were certainly very restricted, and whose utility had not yet been satisfactorily demonstrated. Partial operations, like that of Dr. Baker, were thought to be safer, and, in some cases at least, more successful. The operation recommended by Dr. Mundé has not been practised a sufficient period of time to permit a legitimate comparison with other methods (or none at all) as to the relative length of life afterwards.

Dr. EDWARD WARREN SAWYER, of Chicago, read a paper entitled

SOME REMARKS ON THE OCCIPITO-POSTERIOR POSITION IN VERTEX LABORS; WITH AN ANALYSIS OF THIRTY-EIGHT CASES OCCURRING IN THE PRACTICE OF THE AUTHOR.

After referring to the great disparity existing in the recorded statistics as to the comparative frequency of posterior position in vertex labors, he said that he had met with thirty-eight instances in one hundred and eighty-three labors, or in nearly one-fifth of his vertex cases; in three the occiput was to the left, in thirty-five to the right. Twenty-six occurred in primiparæ, twelve in multiparæ, the greater frequency in the former being due, in his opinion, to the slightly greater density of the tissues in front, by which the back of the child is forced into the back part of the uterus, whereas in multiparæ the relaxation of the parts allows the occiput to occupy the position to which it naturally gravitates, with the back to the front; the excess of the right position over the left is undoubtedly due to the presence of the rectum.

The prevailing idea of the mechanism of posterior vertex positions is that it is the same as in anterior positions, the rotation being more extended (Tarnier, Leischman, Lusk); yet this doctrine is somewhat questioned by some. His own observation was that when the occiput engages in a posterior position it persists in this position, and naturally is delivered in this position, very rarely rotating to the front. In thirty cases out of thirty-eight it was delivered in the posterior position; rotation to the front with the forceps was not attempted.

He next considered the question, How long should the attendant wait for rotation without interfering, when the head is near the inferior strait, before putting on the forceps? After referring to a case of Madame Boivin's, where the woman was delivered of a dead child after waiting forty-eight hours, the mother dying afterwards, he said that in his own experience occurred the following case: the wife of a physician, who had been twenty-eight hours in labor, the head refusing to engage on account of posterior position, he performed version and delivered, but she died in a few hours. In another case he delivered with the forceps successfully after twelve hours. In no instance had he regretted early interference with the forceps, but he had several times regretted too much delay. He had been guided by a simple precept,—viz., not to allow a presentation to remain more than two hours at any point in the parturient canal. After the bag of waters has been drained away there is greater danger to the tissues of the canal.

Referring to the difficulty of ascertaining by the touch alone the position of the presenting head, he said that where the labor goes on, and some difficulty is found in the second stage, this cause should be suspected; it is a condition of danger, and demands the interference of the attendant for the mother and the child. The diagnosis can only be made positively by introducing the hand into the vagina, in order to permit the fingers to ascend in front of the child and detect the superciliary ridge. For this examination the mother should have ether administered.

Having recognized the position, two courses are open for the obstetrician: (1) to deliver with the forceps in the same position, or (2) to endeavor to change it to an anterior position. The latter can only be done by introducing the hand into the vagina, so as to grasp the fœtus and turn the shoulders with the head. It is always difficult to turn a slippery head with the fingers alone. If the attempt fail to turn the shoulders with the head, there is danger of twisting the neck.

Where it is decided to deliver with the forceps in the posterior position, he places the woman upon her left side, and has her under the influence of ether. Tarnier's forceps he regards as very dangerous in this class of cases. He uses his own modification of Simpson's forceps, and applies the blades to the sides of the child's head. The handles of the forceps should be brought well forward, so as to keep the head in complete flexion. When left to nature's unaided efforts, the sharp vertex ploughs through the perineum and may perforate it; with the forceps the perineum may be protected, and the head can be brought down in the occipito-frontal diameter, which is one-fourth inch less than the occipito-mental. The rule is to keep the head flexed. For this purpose he prefers his continuous-curve forceps, which he presented to the profession in 1878. While in the multiparæ the perineum was often saved, it was lacerated in all the primiparæ.

The mortality was as follows: four children were still-born; six others died shortly after birth; one died in the uterus from rupture of the umbilical cord; some may have died from injury with forceps.

He concluded by exhibiting his forceps, and explaining their peculiar advantages for the condition under consideration.

In the extended discussion on this paper, in which Drs. RICHARDSON, REAMY, JOHNSON, HOWARD, ENGELMANN, and the PRESIDENT participated, a general disagreement with Dr. Sawyer's opinions as to the mechanism of occipito-posterior positions was shown, and no particular advantage was accorded to the single-curve forceps. Even the diagram copied from Snelling unfortunately came in for adverse criticism on account of deformity and want of conformity with nature.

Dr. GEORGE J. ENGELMANN, of St. Louis, presented two papers, entitled "Periodical Symptoms in Uterine Disease," and "A Rare and Fatal Form of Sepsis without Symptoms."

The former was read by title, the latter *in extenso*.

A RARE AND FATAL FORM OF SEPSIS.

There is a peculiar form of septic poisoning, due to obscure causes, puzzling in its manifestations, apparently of favorable prognosis, but invariably fatal in its termination. The symptoms are not those of septic poisoning: none of these may be present, or one only and the others absent. The temperature is usually not above the normal, so that the physician who depends upon the thermometer may be deceived and misled into giving a favorable prognosis. These are cases in which a sort of medical intuition is required rather than ordinary diagnostic skill. The text-books and usual authorities do not call attention to this class of cases, perhaps for the very reason that it is difficult to describe a symptomless disease.

Fever and pain are the symptoms most usually relied upon in septicæmia, but here they may both be absent, and the danger is greatest where the symptoms are least or are absolutely wanting. There may be no elevation of temperature, no apparent depression of the vital powers, no profuse sweats, no elevation of the pulse, no diarrhœa with intestinal catarrh. There may be chills, or there may be none: in fact, it is the absence of symptoms rather than their presence which characterizes this form of septic poisoning. The pulse may be slightly rapid and feeble, and there may be some painless looseness of the bowels, or bronchial catarrh, but nothing marked. He must, therefore, take exception to the statement of Dr. Barker that the "symptoms will vary with the quantity of the poison absorbed and the site of the disease," and that the thermometer "is the best means of recognizing the cause, as there is always elevation of temperature," as it had not been confirmed by these cases.

This condition is apt to follow the removal of uterine fibroids and ovariotomy; but it may occur in either sex. These views are not based upon Dr. Engelmann's experience alone; he has had others in consultation with him, who could confirm his statements. He had seen such cases where able professors had denied the presence of sepsis, even until the last day of life. He might mistrust his own observation, had it not been that others had seen the cases with him.

His first case was an elderly gentleman, suffering with enlarged prostate, who had been in good health, and was travelling in Germany. As he was in the railway-cars, he could not empty his bladder when he wished, and a few days later found difficulty in passing his water. A catheter had to be used: still he did not get better. He was in able hands, under the charge of gentlemen connected with Langenbeck's clinic, and careful examinations were made, but no symptoms of disease of any kind were detected. The catheter was passed easily; the urine was clear, but the patient was evidently failing. At the end of six weeks he passed away, comatose, without any symptoms. A post-mortem examination revealed a collection of pus surrounding the kidney, which appeared to be secondary to a small abscess in the prostate gland. The ureter passed through a sac of pus for almost its entire extent. It is strange that this did not produce any effect upon the pulse or temperature; but there was a slight diarrhœa shortly before death, though not a septic diarrhœa.

In a second case, a child died from this form of septic poisoning after diphtheria, which was one of several which he had seen which were precisely alike, without any fever. For several weeks septicæmia was progressing in his body without producing symptoms, until he suddenly had convulsions, and died.

Another case was that of a primipara, a young woman 28 years of age. The child was delivered by the breech, and there was some difficulty in removing the placenta; the perineum was torn a little; no operation was performed, but antiseptic injections were used. Although the temperature was $103\frac{1}{5}°$ and pulse 140 the next day, this soon subsided, and the temperature remained about $98\frac{1}{2}°$ to $98\frac{4}{5}°$. She then expressed herself as feeling well and comfortable, but her abdomen was immensely distended. He was called to see her at this time, and considered the case hopeless. The pulse alone was affected,—it was 104 and depressed; the temperature was normal. She continued thus, feeling well, for several days; but on the fourth day she began to sink rapidly, vomited constantly even fæcal matter, and died comatose. After death her peritoneal cavity was found filled with pus.

The next case of septicæmia was one which was not recognized as blood-poisoning by one of our oldest and best physicians, and, after continuing under his care for four to six months unnoticed, went to its end without being discovered. The case was originally one of fibroids of the uterus in a virgin 56 years of age. There had been hemorrhage and other symptoms of fibroids; she had a discharge of a dark color, foul-smelling, containing shreds of tissue. Her pulse was 80 to the minute, temperature 99°. Coming under his care, he now used antiseptic injections into the uterine cavity, and afterwards powdered the cervix with iodoform; he gave quinine in large doses until her condition gradually changed. He told her physician that she should not be treated locally only, as she was suffering from septicæmia. The discharge afterwards became less, the pulse improved, and she was much better, apparently, from cleansing the uterine cavity. He stopped treatment, and the next day she had a chill, followed by abdominal pain and fever (104°); pulse, 120; but the temperature of the next few days was 98°, $97\frac{3}{10}°$, $97\frac{6}{10}°$, and just before death it was 95° in the rectum. In this case a physician assured the family that there was

no septic poisoning in the case, because of the low temperature.

In another case the patient suffered with pelvic peritonitis. The temperature was only half a degree above the normal, the pulse was either a little accelerated or remained at the normal. There was no pain and no sensitiveness in the abdomen; the patient felt well, but, contrary to expectation, she gradually sank away.

He believed that, as these cases are not infrequent and are usually fatal, they should be recognized. As they are also extremely interesting, he had deemed them worthy of discussion at this meeting.

DISCUSSION.

Dr. RICHARDSON said that he had seen five or six such cases, and would confirm what had been said as to their history and prognosis. The very hopefulness of the patient would lead him to suspect the presence of this form of septicæmia.

Dr. REAMY endorsed the description as far as the slow or not accelerated pulse and low temperature; he had also noticed a sort of mental excitement,—the patient feels very well, and calls especial attention to the fact. He mentioned particularly a class of cases with distended abdomen without elevation of temperature, and also cases of peritonitis without fever, which are closely allied to those mentioned, and likewise prove fatal.

Dr. J. TABER JOHNSON reported a case of a woman on the ninth day after delivery, without ordinary septic symptoms, but she said that she was going to die, although she felt well. There was no elevation of pulse or temperature, but she did die. He thought that the death after diphtheria might be due to some other cause than septic poisoning.

Dr. ENGELMANN closed the discussion, reiterating the principal features of the cases.

The following papers were read by title by the Secretary:

"The Hygiene of Pregnancy," by Dr. Samuel C. Busey, of Washington.

"Rapid Dilatation of the Cervical Canal," by Dr. William Goodell, of Philadelphia.

"The Physiognomy of the Vulva as a Sequence of Anal Disease, and the Cause or Sustaining Cause of Uterine Disease," by Dr. Isaac E. Taylor, of New York.

"The Early History of the Treatment of Vesico-Vaginal Fistule in the United States, and the Statistics of the Several Modes of Operating," by Dr. Nathan Bozeman, of New York.

"Periodical Symptoms in Uterine Disease," by Dr. George J. Engelmann, of St. Louis.

"Contributions to the Topographical and Sectional Anatomy of the Female Pelvis," by Dr. David Berry Hart, of Edinburgh; presented by Dr. Alexander J. C. Skene, of Brooklyn.

"Fibro-Myomata and Fibro-Cystic Myomata of the Uterus: their Diagnosis, Prognosis, Pathology, and Treatment; with Cases and Specimens," by Dr. R. Stansbury Sutton, of Pittsburg.

"On the Ring of Bandl," by Dr. William T. Lusk, of New York.

BUSINESS MEETING.

The annual meeting for private business was held on Wednesday evening, when the reports of the Treasurer and Auditing Committee were read and adopted. The proposed amendments to the constitution and by-laws, which had lain over from last year, increasing the limit of membership to one hundred, were adopted. An amendment proposed by Dr. Emmet last year, making a slight change in the method of election, and requiring that all names of candidates for Fellowship should be brought before the Society by the Council before final action upon them, was also adopted.

Dr. BABCOCK, of London, England, was elected to honorary membership. No active members were elected.

The following officers were elected for the ensuing year:

President.—William T. Howard, M.D., of Baltimore, Maryland.

Vice-Presidents.—W. L. Richardson, M.D., of Boston, Massachusetts; Paul F. Mundé, M.D., of New York.

Secretary.—Frank P. Foster, M.D., of New York.

Treasurer.—Matthew D. Mann, M.D., of Buffalo, New York.

Other members of Council.—Drs. A. Reeves Jackson, H. P. C. Wilson, J. Taber Johnson, and Ely Van de Warker.

The city of Washington, D.C., was selected as the next place of meeting, in September, 1885,—the time of meeting to be the third Tuesday and the two following days.

BANQUET.

The Society was the guest of the Chicago Gynæcological Society at a grand banquet given at the Palmer House on Tuesday evening, at which Dr. A. Reeves Jackson presided. A large number were present, including many prominent members of the local profession.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, September 25, 1884.

The President, JAMES TYSON, M.D., in the chair.

DR. GUY HINSDALE exhibited a model of *phantom brain.*

The model is constructed in colossal proportions, and is intended to show the course of the fibres in the human brain, and their

relation to the several nuclei and to the spinal cord. The preparation has been recently purchased for the Mütter Museum of the College of Physicians, and was constructed by Buechi, of Berne, Switzerland, under the supervision of Prof. Acby.

Its height is one hundred and twenty-five centimetres; its width, seventy centimetres. The cortex is dotted over with numerous corks, two centimetres long, which are distributed in systematic order. The basal nuclei, of a much larger size, are seen in their appropriate places. The spinal cord, made up of ganglia and columns of wires of different colors, is represented throughout a portion of the cervical region. These columns of the cord, of different colors to distinguish their function, lead to their appropriate ganglia of corresponding color, or to the areas in the cortex which are marked by similarly-colored corks.

Taking first the anterior and lateral columns of the cord painted red, we can trace these motor fibres to the anterior and lower portion of the medulla, where they decussate, through the pons, to the internal capsule, where, between the caudate nucleus of the corpus striatum and the optic thalamus, they radiate to the cortex. They are seen to come chiefly from the convolutions about the fissure of Rolando. When red balls are seen from that point, a red motor fibre descends to the anterior or lateral columns. It will be seen that the column of Türck, or direct pyramidal tract, is in relation with the posterior part of the lateral column of the opposite side. As regards the exact localization of the sensory and motor tracts of the spinal cord, there is still some discrepancy of opinion. Prof. Ferrier states that the antero-lateral columns are usually regarded as the chief motor paths. but quotes the more careful experiments of Ludwig and Woroschiloff (1874), who place the motor paths in the lateral columns only. The anterior columns (of Türck) are regarded more as commissural connections between the motor nerves and adjacent segments, and at least not the direct paths of motor impulses proceeding from the brain.

Tracing the fibres of the posterior columns, colored blue, we find them represented as wholly decussating in the medulla, forming the posterior third of the internal capsule, thence passing to the corpora quadrigemina and optic thalami, colored blue, which are the great centres of sensation.

The external portion of the lateral columns, colored green, are seen to lead to the cerebellum, decussating near its superior surface. The yellow fibres of the model place the basal nuclei in communication with the cortex; the white fibres, constituting the corpus callosum, are purely commissural. The columns of the cord, as represented in the model, correspond precisely with the arrangement given by Flechsig, and endorsed by Charcot and Hammond. Ludwig and Woroschiloff* argue that "a vicarious interchange of function potentially exists between different parts of the cord." Ferrier admits that, in determining the course of the cerebral fibres, anatomy reveals very little, and that physiological experiment is practically the only means at our command. Many more observations and experiments will have to be made before it can be said that the sensory and motor paths have been exactly defined, and all views reconciled.

A case of infantile mollities ossium. Presented by Dr. CHARLES MEIGS WILSON for Mr. CLINTON DENT, of St. George's Hospital, London.

This specimen was sent to me by Mr. Dent, the well-known editor of the English edition of Billroth's "Notes on Clinical Surgery." The following history was also furnished by Mr. Dent: "This specimen shows the inner vertical half of the right femur of a child æt. 16 months. There is a pseudo-fracture of the bone. The medullary canal is filled up, and a considerable deposit of enveloping callus maintains the fragments in apposition. The entire bone is unnaturally soft, and in the recent state showed this peculiarity still more strongly. The bone was removed post mortem from the body of a feeble, ill-nourished child. No history of syphilis was obtainable from the parents, and the child showed no evidence of congenital syphilis. Some of the ordinary symptoms of rickets were observable,—*e.g.*, bending of the ribs, general tenderness, enlargement of the wrists, etc. No symptoms of scurvy were present. It was evident that there was much more than rickets in the condition. When the child was first admitted to the hospital, there were pseudo-fractures of the right humerus and left tibia, besides the fracture of the right femur. The humerus, which was bent at a right angle, was forcibly straightened. It bent like a bar of soft metal, and remained in the new position; it was, however, put in a light pasteboard splint. Subsequently, with the removal of the splint, the bone again gradually bent, and was again forcibly straightened. While in the hospital under observation, the femora became affected in the usual place,—*i.e.*, a little below the trochanters. Some swelling and tenderness were noticed; and then, although the child was kept constantly in bed, the bones became bent. Ultimately, in about ten days, the pseudo-fractures became complete. Great improvement of general health, as evidenced by rapid increase of weight, resulted from treatment by rest, good diet, and cod-liver oil. The child finally died with an attack of whooping-cough, after having been under observation a few weeks."

This is a very rare form of bone-disease,

* Ferrier, Functions of the Brain, p. 5. London, 1876.

especially in the young. It is seen occasionally in England, never with us. The pathological changes seem to be of a retrograde character: sometimes lipomatosis takes place; sometimes there is a metamorphosis, first into cartilage, and then into embryonic tissue. This specimen shows, in different portions, both changes. The disease is attended with marked fatality. In this specimen the cortical substance is attenuated, and the medullary cavity is enormously enlarged. The bone seems deficient in lime-salts. Some authorities believe that to the lactic acid found in the chemical analysis of such bones this change is to be attributed; but this fact is mentioned only in order to elicit discussion. Other observers have found enormous quantities of oxalate of lime in the urine of patients with malacosteon. One curious fact is the effort which nature makes to repair the fractures, as shown in this specimen. This callus seems deficient in inorganic matter, and is destined eventually to be reabsorbed. Syphilis, scrofula, and scorbutus have all been assigned as causes of the affection. Most authorities, denying the existence of the disease in children, assign it to middle life, and speak of it as being lighted up or aggravated in women by pregnancy.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held September 24, 1884, GEORGE F. SHRADY, M.D., President, in the chair.

MALIGNANT DISEASE OF THE LUNG AND MEDIASTINUM.

Dr. VAN GIESEN presented the specimen, for which he was indebted to Dr. French. The patient was aged 41 years, a German. She was admitted to the hospital September 11, 1884. Over the upper portion of the right lung there was entire absence of the respiratory murmur, of vocal fremitus, and of dulness on percussion. The patient was much emaciated. There was œdema of the left upper eyelid. There was no œdema of the extremities. There were tympanites and dyspnœa, cough without expectoration, nausea without vomiting. The physical signs over the left side of the chest were normal. There was no history of cancer in the family. Death ensued on the 16th of September. The brain was not examined. The heart was normal. The pericardial sac contained eight ounces of clear serum. In the anterior mediastinum was a mass of hard, cancerous glands, of the size of the fist. The upper part of the right lung was infiltrated with hard, cancerous tissue. The remainder of the lung, with the exception of some adhesions at the base, was healthy. The left lung was normal. The bronchial glands were enlarged. The right bronchus was constricted to the size of a No. 8 English catheter.

The spleen was normal, as were also the kidneys. The liver was slightly fatty. Unfortunately, the uterus was not examined. An imperfect microscopical examination pointed to sarcoma of the mediastinum and lung.

This was the fourth or fifth case seen by Dr. Van Giesen within the past three years, and he had found an important feature in the diagnosis to be absence of vocal fremitus. Usually in cases of condensation of the lung we expected to find vocal fremitus more or less exaggerated. In the present instance we could readily account for its absence by the closure, nearly complete, of the right bronchus.

With regard to œdema of the eyelid, this was present also in one of the other cases, due, as Dr. Van Giesen believed, to pressure upon the vessels of the corresponding side by the enlarged glands.

PHAGEDENIC SYPHILIDES.

Dr. WYETH presented a hospital patient, aged 35 years, a native of Germany, who was admitted on the 11th of July. The patient had had gonorrhœa on several occasions, the last attack being eight months before his admission, but he gave no history of syphilis until five and a half weeks prior to July 11, when he had connection with a prostitute, and one week later noticed what looked like a blister, a quarter of an inch in diameter, at the base of the penis. He had not been with a woman previous to this time for some weeks. The sore remained stationary about ten days, and then began to enlarge and become painful. Before admission the sore on the penis and groin was treated with iodoform and charcoal poultices. It had attained to considerable size, and was deeply excavated. On admission there was a slight pustular and papillary eruption over the face and extremities. The glands were enlarged. There was a sore on the tongue, and some elevation of the temperature. When Dr. Wyeth first saw the patient, August 7, the eruption was well established, and at places, especially on the nose, presented the appearance of lupus, but it was evident from the history that it was a phagedenic syphilide, which had come on in the early stage of the constitutional affection. Dr. Wyeth thought this case illustrated the statement of Bumstead and Taylor, that a pustular syphilitic eruption was apt to follow the phagedenic syphilitic ulcer, and the violence of the disease was in many cases proportionate to the violence of the initial lesion. Up to the time that he saw the patient, blue mass had been administered in small doses, but without apparent effect. He then gave him increasing doses of the proto-iodide of mercury until the effects had become manifest. He thought the strongest proof of the specific origin of the eruption was its response to the anti-syphilitic remedy.

Referring incidentally to the treatment, Dr. Wyeth said he regarded mercury as the remedy for syphilis, just as quinine was the remedy for malaria. Nevertheless, there were many cases of a mild nature, and the patients may get well without any medicine whatever. Indeed, one might well prefer syphilis to pneumonia or typhoid fever.

Dr. LEVY spoke of the importance of administering tonics when indicated, and the PRESIDENT said that he had often found a tonic course of treatment all that was necessary.

REVIEWS AND BOOK NOTICES.

MALARIA AND MALARIAL DISEASES. By GEORGE M. STERNBERG, M.D., F.R.M.S., Major and Surgeon United States Army, Member of the Biological Society of Washington, late Member of the Havana Yellow Fever Commission of the National Board of Health, Corresponding Member of the Epidemiological Society of London, etc. 8vo, pp. 329. New York, William Wood & Co., 1884.

Dr. Sternberg's eagerly-looked-for book is an extremely important and valuable number of the Messrs. Wood & Co.'s current annual series. The author has brought to the difficult task of its preparation lively interest in the subject, long familiarity with the obscure problems relating to malaria and its alleged causes, practical knowledge of malarial diseases, and, to regulate all, the scientific spirit. The result is an able presentation and review of the facts as they at present stand. To those positive persons who must have a theory for all things, this book will prove a disappointment. The author has fully recognized that the unsolved problems connected with the subject are not to be settled with the pen,—a fact that he is in the very best position to know. He has, therefore, presented his case as it stands, realizing that further evidence must be submitted ere a verdict can be reached.

But to those who desire the known facts concerning the periodical diseases gleaned from the experience of the best observers in all regions of the world where they prevail, with a full exposition of current theories and an uncompromising criticism of the same, this book will be welcome and useful. It should be read by every practitioner of medicine, we were about to say, from St. Johns to Santa Barbara,—the ancient phrase is better, from Dan to Beersheba,—for malaria is widely prevalent. J. C. W.

THE REFRACTION OF THE EYE. By GUSTAVUS HARTRIDGE, F.R.C.S. J. & A. Churchill, London, 1884.

This little work supplies a want, and need only to be examined by those beginning the study of refraction to be appreciated. The first chapter is devoted to some general principles of optics; the second, to the refraction of the eye, accommodation, and convergence; the third, to the diagnosis of refraction errors; and succeeding chapters to hypermetropia, myopia, presbyopia, astigmatism, etc. Quite a full description of retinoscopy is given, and also some account of the ophthalmometer of Taval and Schiötz. A series of test-types is appended. The book is well printed, and the illustrations are numerous and excellent. Two criticisms only suggest themselves to us:

1. That the large and important works on Anomalies of Refraction by Mauthner and by Nagel (Graefe u. Saemisch, Handbuch der Augenheilkunde) seem not to have been consulted in the preparation of the book.

2. The error common to many medical books of not defining with exactness the facts and observations which are presented. Thus, in speaking of the shortening of the axis in hypermetropia, our author says, "So constant and regular is this decrease that from the amount of hypermetropia can be estimated the diminution in length of the axial line." Upon this principle a table is constructed showing the amounts of shortening which occur in different degrees of hypermetropia. Now, this is erroneous. The error results from not defining with exactness the statement that hypermetropia is due to shortening of the axis of the eye. One cannot, by taking the length of the diagrammatic eye and calculating the shortening which would occur in a given grade of hypermetropia, say that that amount of shortening exists in an actual case of hypermetropia. We commend, however, this book as one which will add to the reputation of the author. H.

HAND-BOOK OF THE DIAGNOSIS AND TREATMENT OF SKIN DISEASES. By ARTHUR VAN HARLINGEN, M.D., Professor of Diseases of the Skin in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. With Two Colored Plates. Philadelphia, P. Blakiston, Son & Co., 1884. 8vo, pp. 282.

This new hand-book is essentially a small encyclopædia of pathology and treatment of skin diseases, in which the subjects are arranged alphabetically. This arrangement was that followed by the late Tilbury Fox, of London, in his hand-book, which, we believe, was remarkably successful; and we have no doubt that it will be equally appreciated in the present work, which (compendious in form) contains a very complete summary of the present state of dermatology. Dr. Van Harlingen's position in the profession, being at present Vice-President of the American Dermatological Association, which he served as Secretary for several years, and the high standard of his communications to his department, are sufficient to warrant the confidence

in his teachings which is fully sustained by an examination of this hand-book, which we heartily commend for its brevity, clearness, and evidently careful preparation.

THE PEDIGREE OF DISEASE: BEING SIX LECTURES ON TEMPERAMENT, IDIOSYNCRASY, AND DIATHESIS, DELIVERED IN THE THEATRE OF THE ROYAL COLLEGE OF SURGEONS IN THE SESSION OF 1881. By JONATHAN HUTCHINSON, F.R.S., late Professor of Surgery and Pathology in the College; Emeritus Professor of Surgery in the London Hospital; President of the Ophthalmological Society, etc., etc. 8vo, pp. 136, London, J. & A. Churchill, 1884.

These lectures, delivered in June, 1881, now reprinted in book form, are thus happily rescued from the oblivion of their first appearance in one of the medical journals. Why the author should have so long delayed their publication in the present form is not apparent. His admission that the commendation bestowed upon them by Sir James Paget last year induced him to publish them now shows how near they came to not being republished at all. That would have been a serious loss to medical literature, notwithstanding its oppressive abundance. This kind of work is far from abundant: would it were more so! When we think of the author's work, the Virgilian "Felix qui potuit rerum cognoscere causas" comes to mind; and these lectures are in his best vein. Dealing with a group of cognate subjects that are little thought of and still less understood, yet of eminent practical importance; written in a style at once lucid and attractive; clear, learned, and reasonable, these lectures will be read with equal interest and profit by those clinicians who seek to temper their knowledge of things with knowledge of the causes of things.

J. C. W.

DISEASES OF THE HEART AND THORACIC AORTA. By BYROM BRAMWELL, M.D., F.R.C.P.E., etc., etc. With 317 Illustrations. 8vo, pp. 783. Edinburgh, Young J. Pentland, 1884.

It affords us pleasure to commend in the strongest terms this excellent treatise. In doing this, we are prepared to reply, to any challenge that may be made as to our reasons,—first, that Dr. Bramwell's work is literally *excellent* among recent books upon the heart in convenience of arrangement and in comprehensiveness; second, that it is singularly full and clear in the sections on pathology; and, third, that the subject of treatment is handled with judgment and brought up to date.

The full-page lithographs are of great general value, and will be especially useful to those students and practitioners whose opportunities in the dead-houses of hospitals or in museums are few and far between. J. C. W.

GLEANINGS FROM EXCHANGES.

"THE LANCET" ON MODERATE DRINKING AND TEETOTALISM.—At the recent Health Exhibition in London the subject of intemperance was discussed, and the use of alcoholic liquors condemned in no measured terms. The *Times* thereupon published a leading article defending moderate drinking, and stated that teetotalers are persons of inferior physical development, and, so far as they can be judged by facial expression, not "remarkable for intellectual power," the best work of the world being done by the moderate drinkers. On the whole, it was concluded that teetotal societies do very little good and a great deal of harm. The *Lancet*, in commenting upon this, without attempting to defend the dogmatism of temperance reformers, says, "We cannot much approve of the article in our contemporary, but it is rather of its tone and spirit than of its substance that we have to complain; rather with its scant and reluctant praise—its actual dispraise—of men with a great cause and with good motives, than with its scientific propositions, that we have to quarrel. The world is not so much in danger of neglecting to take a proper amount of alcohol that it needs three or four columns of ingenious argument to prevent it falling a prey to indigestion and nervous exhaustion from drinking water alone. But the excuse for such writing would be less if there were a little more reasonableness and temperance on the part of those who seek to abate the national consumption of alcohol. Their case is by no means so contemptible, logically and medically, as the writer referred to above would make out. There are some very good looking fellows among them; they are not by any means intellectually contemptible; they live quite as long as, if not longer than, other people, and escape many diseases that affect others, though they have their own liabilities. They are good workers. There may not have been yet a teetotal Shakspeare or Milton,—there has not been time; but much of the best work of the world nowadays is done by men who either do not use alcohol, or use it in such quantities as to be inoperative physiologically or pathologically. And the common work of the world is done well by abstainers: they are industrious, reliable, healthy. According to Lord Wolseley, they make good soldiers. Sir William Gull has said that 'it is one of the commonest things in our society for people to be injured by drink without being drunkards. It goes on so quietly that it is very difficult to observe. To the professional eye the effect is perfectly marked and distinct.' Many other eminent men have given similar testimony. So that there is an amount of drinking deemed moderate by society which, in the opinion of judges, is very injurious to the liver, the lungs, the nervous

centres, etc. Further, the actual impression made by the teetotal school on public opinion and social habits is considerable, so that sensible men do not take stimulants in the quantities they used to do, or on an empty stomach and without food. No doubt much of this is due to sounder medical science, and to the extreme moderation of medical prescription and example. But part of it is due to teetotalism and to religious efforts to promote sobriety, which it should be the desire of every one to second, the more so as there is still a frightful amount of ignorance abroad as to the impunity with which alcohol, even in strong forms, may be taken into an empty stomach. A physiologist may still be shocked every day in a restaurant or a railway refreshment-room —of course physiologists never go into public houses—by seeing young men order and toss off without thought and without food glasses of spirit more or less raw. He knows how infallibly and how quickly that leads to mischief. But for evils and follies like this there is room for common protest and effort, apart from intemperate doctrines of teetotalism on the one hand, and too easy disparagement of those who hold them on the other."

Abortions, and Elixirs containing Strychnine.—Dr. George Pringle, in a communication to the Canada *Lancet*, points out a new danger from the use of the favorite elixirs containing strychnine. In three cases out of four, in which pregnancy was not suspected, the use of strychnine with a chalybeate brought on an abortion, and the fourth had symptoms of abortion which passed away on stopping the treatment, and again returned upon resuming it, so that the remedy had to be abandoned, and a tonic without the strychnine substituted. He advises that strychnine should not be given after conception has taken place, and that manufacturers should omit both strychnine and arsenic from elixirs sold to supply popular demand.

MISCELLANY.

The Criminality of Cannibalism.—The criminality of cannibalism committed by starving men is soon to be tested in an English court, under peculiar and interesting circumstances. The English yacht "Mignonette" was cast away in the South Atlantic Ocean, and the crew, consisting of the captain, two men, and a boy, were obliged to take to the boat. They drifted about in the open sea for a number of days until all their food was exhausted. They were fortunate enough then to kill a turtle, and thus sustained life for a time. When this was gone, they talked of drawing lots to see who should die for the others. This not being agreed to, and the boy becoming very weak and apparently about to die, the captain decided to kill him in order to save the lives of the others.

After calling upon God to pardon the act, he killed the youth, and the three survivors were kept alive by eating his flesh until a passing vessel picked them up. The facts were not concealed, and the act was not seemingly considered criminal, but on arrival in port the captain was arrested, and his trial is soon to take place for murder. The trial will bring out the fact that unless the captain had done as he did, the lives of all would probably have been lost; but the moral effect of the deed may not be affected by this circumstance. It will also be shown that the four had been tossed about for fifteen days in an open boat, without food, before consenting to the killing; and it will be a matter for consideration whether a person is responsible for his acts under such circumstances.

Ownership of Medical Specimens.—A case involving the right to a medical specimen has just been before a court in Petersburg, Virginia. A person suffering from some internal complaint, which kept him remarkably thin, although enjoying a ravenous appetite, solved the problem of his ailment by ejecting a dead lizard some ten inches long. The curious object was thrown away, but was found and preserved in alcohol by a physician. This was ascertained by the brother of the reptile-ejector, who was also a physician, and was demanded by him from the finder. The latter consented to give it up if he were repaid the cost of preserving it. This was refused, and suit brought to recover the specimen. On the trial in one of the inferior courts judgment was given requiring the finder to give it up. This verdict has been appealed from, and the matter is undecided.

A Suit against a Dentist.—A San Francisco dentist has brought upon himself a heavy verdict for damages in the following way. He agreed with a patient to fill her teeth for seventeen dollars and a half, but demanded five dollars more upon the completion of the work, and, when she declined to pay that amount, forcibly removed the fillings. Suit was then brought for damages, and the jury has just awarded a verdict for two hundred and seventeen dollars and a half, besides costs of the suit.

Dr. Delafield, of New York, will read a paper on "Broncho-Pneumonia" at the next semi-annual meeting of the Pathological Society, to be held at the College of Physicians and Surgeons, Thirteenth and Locust Streets, October 23, at eight o'clock P.M. The members of the profession generally are cordially invited.

A Death from Ether occurred at the St. Mary's Hospital, in this city, on the 14th instant, a report of which is deferred until the result of the autopsy can also be published.

NOTES AND QUERIES.

TREATMENT OF MIGRAINE.

To the Editor of the Philadelphia Medical Times:

In the *Bulletin Général de Thérapeutique* of August 30, 1884, there is a statement accredited to your journal that bromide of potassium and deodorized tincture of opium in combination may be considered "almost a specific" for the pains of migraine. I wish to add my testimony to the efficacy of this treatment, or one which is virtually the same. Since my earliest recollection I have been a sufferer from this affection, and after trying guarana, caffeine, bromide of potassium alone, and every other agent which could be thought of, and enduring an amount of torture which those only can appreciate who have themselves been sufferers, I have found prompt and invariable relief from a combination of bromide of potassium and morphia, or bromide of potassium and codeia. I can count on relief in half an hour after taking thirty grains of bromide of potassium and one-third of a grain of morphia or three-quarters of a grain of codeia, and so complete is this relief that I have more than once been able to perform delicate operations when an hour before I could not hold up my head, and when my hand had been so tremulous that I could scarcely hold a knife. Within the past fortnight I have tied the common carotid under just such circumstances, and a few months ago I had to do a tracheotomy under like conditions.

No doubt many other physicians have employed this combination with advantage. Indeed, so rational did the treatment seem to me that I should never have thought of mentioning it but for the extract from your journal which has just come to my notice.

Yours respectfully,
Wm. C. Dabney, M.D.

Charlottesville, Virginia,
October 7, 1884.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM SEPTEMBER 28, 1884, TO OCTOBER 11, 1884.

Clements, B. A, Major and Surgeon.—In addition to present duties, to take charge of the office of the Medical Director of the Department during the temporary absence of that officer. Paragraph 1, S. O. 195, Department of Missouri, September 29, 1884.

Happersett, John C. G, Major and Surgeon.—Will be relieved from duty in Department of the East, and ordered for duty at Willet's Point, New York.

Woodruff, Ezra, Captain and Assistant-Surgeon.—Granted leave of absence for four months.
S. O. 235, A. G. O., October 7, 1884.

Bentley, Edwin, Major and Surgeon.—Granted two months' leave of absence, with permission to apply for two months' extension, to take effect upon assignment to duty in Department of Texas of Surgeon F. L. Town. S. O. 121, Headquarters Division of the Missouri, September 30, 1884.

Barthole, John H., Captain and Assistant-Surgeon.—Assigned to duty at Fort Ringgold, Texas, as post surgeon. Paragraph 5, S. O. 129, Headquarters Department of Texas, September 25, 1884.

Cronkhite, Henry M, Captain and Assistant-Surgeon.—Assigned to duty as post surgeon, Fort Reno, Indian Territory. S. O. 197, Department of Missouri, October 2, 1884.

Loring, Leonard Y., Captain and Assistant-Surgeon.—From Department of the East to Department of California.

Harvey, Philip F., Captain and Assistant-Surgeon.—From Department of Dakota to duty in Attending Surgeon's Office, Washington, D.C., relieving

Shufeldt, Robert W., Captain and Assistant-Surgeon,—who, on being relieved, will report to commanding general, Department of Missouri, for duty.
S. O. 237, A. G. O., October 9, 1884.

Crampton, L. W., Captain and Assistant-Surgeon.—Granted leave of absence for one month and ten days. S. O. 60, Headquarters Division of the Atlantic, October 2, 1884.

Powell, J. L., Captain and Assistant-Surgeon.—Granted leave of absence for one month, on surgeon's certificate of disability.

Spencer, William G., Captain and Assistant-Surgeon.—Granted leave of absence for one month
S. O. 204, Headquarters Department of the East, October 8, 1884.

McCreery, George, First-Lieutenant and Assistant-Surgeon.—Assigned to duty at Fort Meade, Dakota Territory. S. O. 115, Headquarters Department of Dakota, October 6, 1884.

Gibson, R. J, First-Lieutenant and Assistant-Surgeon.—Assigned to duty as post surgeon, Fort Winfield Scott, California, relieving Assistant-Surgeon A. S. Polhemus.

Polhemus, A. S., First-Lieutenant and Assistant-Surgeon.—Upon being relieved, to report to commanding officer, Fort McDermit, Nevada, for duty as post surgeon.

White, R. H., Captain and Assistant-Surgeon.—To report to commanding officer, Angel Island, California, as post surgeon, relieving Assistant-Surgeon C. K. Winne.

Winne, C. K., Captain and Assistant-Surgeon.—Upon being relieved, to report to commanding officer, Benicia Barracks, California, for duty as post surgeon, relieving Surgeon C. C. Byrne.
Paragraph 1, S. O. 115, Headquarters Department of California, September 23, 1884.

Taylor, A. W., First-Lieutenant and Assistant-Surgeon.—Assigned to duty at Fort Omaha, Nebraska. Paragraph 3, S. O. 87, Headquarters Department of the Platte, October 3, 1884.

Everts, Edward, First-Lieutenant and Assistant-Surgeon.—Granted leave of absence for one month, with permission to leave the limits of the Department. S. O. 145, Headquarters Department of Colorado, September 24, 1884.

Black, C. S., First-Lieutenant and Assistant-Surgeon.—Granted leave of absence for fifteen days, to take effect this date. Paragraph 3, S. O. 131, Department of Texas, September 29, 1884.

LIST OF CHANGES OF STATIONS OF NAVAL MEDICAL OFFICERS FROM SEPTEMBER 28, 1884, TO OCTOBER 11, 1884.

Surgeon Henry Stewart, granted leave of absence for one year, with permission to leave the United States, October 15, 1884.

P. A. Surgeon John M. Edgar, detached from the "Nantucket," and placed on waiting orders, September 29, 1884.

P. A. Surgeon G. E. H. Harmon, to the Naval Academy, September 30, 1884.

P. A. Surgeon D. N. Bertolette, from the Naval Academy to the "Dolphin," October 4, 1884.

P. A. Surgeon Benjamin F. Rogers, to the Naval Academy, September 30, 1884.

Surgeon George H. Cooke, from the Naval Academy, and placed on waiting orders, October 2, 1884.

P. A. Surgeon Robert Whiting, from the Naval Academy, and placed on waiting orders, October 4, 1884.

P. A. Surgeon G. C. Lippincott, granted sick-leave, October 4, 1884.

P. A. Surgeon Robert Whiting, to the Naval Hospital, New York, October 6, 1884.

P. A Surgeon S. A. Brown, resignation accepted, October 7, 1884.

Surgeon George R. Brush, detached from the "Vandalia," and placed on waiting orders, October 8, 1884.

P. A. Surgeon Thomas C. Craig, detached from the "Vandalia," and placed on waiting orders, October 8, 1884.

Surgeon Joseph G. Ayers, leave of absence for one month, October 10, 1884.

Surgeon A. S. Oberly, to the Naval Hospital, Portsmouth, New Hampshire, October 10, 1884.

Medical Inspector C. J. Cleborne, detached from duty at Portsmouth, N.H., and placed on waiting orders, October 10, 1884.

P. A Surgeon John W. Steele, detached from the "Brooklyn," and placed on waiting orders, October 10, 1884.

P. A. Surgeon John C. Boyd, to duty at Navy-Yard, Washington, D.C., October 10, 1884.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON SYPHILITIC SEQUELÆ (TERTIARY SYPHILIS) RESULTING FROM SYPHILIS ACQUIRED IN UTERO.

BY FESSENDEN NOTT OTIS, M D.,

Clinical Professor of Venereal Diseases in the College of Physicians and Surgeons, New York.

TERTIARY SYMPTOMS OF INTRA-UTERINE SYPHILIS.

GENTLEMEN,—Here is a little, but not very young, patient, whom I first saw a few moments ago. He is 18 years of age. The grandmother, who is with the lad, intimates that the mother of the boy was of rather obscure origin, and claims that the difficulty in the case originated on her side. It was a year and nine months from the date of the marriage that this child was born; she further states that the mother and the father both had an eruption within that time. It is evident from the general appearance of this boy that he is suffering at the present time from the late lesions of syphilis. These lesions are in line with those which we were speaking about last week, changes in the bone-substance in various localities as a result of damage to lymphatic spaces and channels in various localities, and which, after periods varying from two or three to fifty or more years, become obstructed or obliterated, causing localized accumulation of lymphatic fluid and lymph-cells, constituting what is usually termed *gummy material.* This gummy material, as I have previously explained to you, has been found to form the only constant abnormal constituent of every lesion of late or tertiary syphilis,—whether the lesion be known as a *gummy tumor*, or a *tubercular syphilide*, or a *syphilitic node*, or any other sequel of syphilis. I have also shown you that this gummy material, so called, possesses neither corrosive nor contagious properties, but that the damage caused by its presence is chiefly, if not wholly, mechanical, causing destruction by pressure, obstruction of blood-vessels, etc. In our last lecture I called your attention especially to two forms of syphilitic sequelæ which were strikingly in proof of this statement,—viz., the tubercular lesions of syphilis, which often pursue their course without ulceration, and yet leave cicatricial depressions showing loss of tissue by absorption, from the mechanical influence of the gummy infiltration in the skin; and, secondly, the losses of bone-structure which, on the skull especially, cause depressions without either inflammation or suppuration. These syphilitic sequelæ were traced back, in every case presented, to an initial lesion of syphilis, and various characteristic lesions of the active or contagious stage of syphilis were shown to have intervened between the initial lesion and the sequelæ. The cases shown were all adults. In the present instance the patient is a child. Both its parents were subjects of an eruption, which, although eighteen years ago, the grandmother remembers distinctly to have been after the marriage, and before the birth of the child. She states that it was thought to be a bad disease, and claims that it was communicated to her son by the mother of this boy.

The grandmother states, further, that the patient was not much under her observation during its early childhood, but she observed its little neck, big head, and later, at five or six years, she saw an eruption which covered the entire body, leaving depressions or scars after its disappearance.

I think there can be no question, gentlemen, that this trouble was acquired in utero, and that the initial lesion was in utero; that is to say, that the initial period of the disease was in utero. Of course there was no localized abrasion; the poison was introduced into the circulation directly; there was no period of incubation. The description of the general appearance of the child as given by the grandmother suggests a syphilitic diathesis. The eruption she saw after the fifth year was not characteristic of the eruptions of the early stage of syphilis, but of the tubercular eruptions which in the adult appear at any period after the second—usually between the second and seventh—year.

As we strip this child,—for, although eighteen years old, in body and mind he is still a child,—we see numerous scars resulting from the tuberculous eruptions he has suffered from. But the most prominent evidence of the effects of the disease as we see it now is in the bones of the head and face, and on the cranium in par-

ticular. Passing my hands over the head, I find that there are evidences of that sort of bone-trouble alluded to last week under the subject of dry caries of Virchow,—a form of lesion of bony structure that is more characteristic of syphilis than any other lesion, and which is evidently the result of pressure of the so-called gummous material localized between the external and internal tables of the skull. In some cases this process goes on to ulceration, while in many others there is no ulceration from the first to the last. Consequently, as I before remarked, the term caries, as applied to this trouble, is a misnomer. The change is not the result of caries, as we cannot have caries without suppuration, without that peculiar form of destruction which comes on from an ulcerative process, and there is no ulcerative process here. We have present here several such points where there have been no open sores, while there is also, as you see, a large open bony ulcer on the top of the head. Here on the front part of the hairy portion of the scalp is a marked circular depression. It is said that the boy had a fall and struck there. The depression appears as though it might have been so caused, and yet it is the same sort of depression which occurs in similar cases without any inflammatory process whatever,—a swelling or a bulging which may disappear, and sometimes leaves a depression of bone, without any inflammation having been apparent during its entire course. Yet conditions may be present which shall lead to suppuration in some cases. Let, for instance, the gummous tumor go on to a considerable size and attract attention, while the patient is in good condition there will be no special trouble from it; but if he be in depressed condition a suppurative process may commence which will go on (often producing great havoc in the bony tissues) until arrested by a change in the patient's circumstances or by treatment. So that depressing influences, anything to deteriorate the condition of the patient, may change a so-called simple dry caries into an open ulcerative condition, such as you see here. I have often seen these nodes of considerable size develop without pain of any consequence, without evidence of inflammatory trouble, and then disappear more quickly than they arose, under the influence of the mixed treatment,—the mercurial and the iodide of potassium,—within perhaps a few weeks, whereas if they had been let alone an inflammatory process might have been set up, when this material would have taken on suppuration, and there would have been true loss of tissue by ulcerative process.

We notice here that the bones of the nose have been carried away; there has been loss of bony material of the forehead, and general disfigurement of the head and body. This boy, eighteen years of age, is not larger than most boys of five. The effect of the disease has been to stunt, retard the growth in every respect. Exactly how it does so is pretty difficult to say. But where we find a positive lesion, a localized point of trouble, in these cases, it is in line with what we know occurs late in specific disease in the adult, and the same course of treatment would be indicated. The chief interest in the case is the history of the acquirement of the disease in utero, and its illustration of the fact that when so acquired it develops exactly the same as when occurring in the adult.

What I wish particularly to demonstrate and illustrate by this case is that the disease pursues the same course in every living organism as far as that organism is capable of developing it,—in the infant, in the youth, in the adult,—apparent differences being readily accounted for by the differences in the maturity and stability of the tissues; that while in this case we have a history of so-called hereditary syphilis, the conditions in which it has resulted do not differ in any respect from syphilitic sequelæ following acquired syphilis in the adult; that the lesions are not the effect of a vitiated *hereditary diathesis*, but, as far as a single case can go, it gives support to the view I have long held, that syphilis in the infant, in the embryo, or the ovum, is the result of direct contact of its germinal cells with the contagium of syphilis through the blood of the mother. The claim often made that syphilis is or may be communicated to the embryo through the influence of the male parent directly is disproved by the fact, demonstrated by the experiments of Mireur and others, now accepted by all recent authorities, that the semen does not contain the contagious property of syphilis. Syphilis must, then, first be communicated to the mother before it can reach her unborn child. According to the views previously set before you demonstrating the

material nature of syphilitic infection, the first requirement to that end is an organism free from syphilis; second, contact with the syphilitic contagium or principle. It has been practically demonstrated that the secretion of the sequelæ of syphilis, the so-called "gummy material," is free from a contagious property. The contagium of syphilis is comparatively short-lived; the contagious property in the blood has been so amply proved by the statistics of Fournier that it must be accepted as a rule that it does not last more than two or three years.* The power of this contagium, then, to transmit disease through generations cannot be admitted, any more than the power of the contagium of smallpox. This position is the legitimate and necessary sequence of the material views of the nature and behavior of syphilis which I have held and taught for the past fifteen years. Mr. Jonathan Hutchinson, in his lectures on the "Pedigree of Disease" in 1881 (published in London, 1884), says, page 90, "A child, then, I assert, *inherits syphilis in precisely the same sense and in precisely the same manner as it may inherit smallpox.* It inherits, not the *diathesis*, but the *disease.*" "The reason why," he says, "the inheritance of smallpox is very rare, whilst that of syphilis is unfortunately common, is simply that the period during which the virus is extant in the blood is very different in the two cases." He claims that the clinical facts generally known in regard to the syphilis of infants afford proof that the *diathesis* of syphilis is as incapable of transmission as that of any of the exanthemata, and he concludes that "*no mitigated transmission is possible;* that the child gets either nothing at all, or the germs of the disease, and that in the latter case they will, subject to the laws of idiosyncrasy, develop equally in all cases." Mr. Hutchinson, generally conceded to be the greatest English authority on syphilis, thus distinctly supports the germ theory of syphilis, and carries it to the legitimate conclusion that the disease is confined in every instance to the individual organism infected, and hence that it is incapable of being acquired or communicated through hereditary transmission; in other words, that *there is no such disease as hereditary syphilis*, any more than there is an hereditary smallpox, and that in every case of syphilis the disease is *acquired* through contact with a disease-germ of syphilis in an organism previously free from that disease, whether it occurs in the ovum, the embryo, the fœtus, the infant, or in the adult. This is exactly the position which is taken by me in the chapter on "Syphilis of Infants and Hereditary Syphilis," in my book on Genito-Urinary Diseases and Syphilis, published by Bermingham & Co., New York, 1883, page 204 *et seq.*, and more fully discussed in an article prepared for the second edition of that work and published, from advance sheets, in the first number of *The Esculapian* (edited by Ed. J. Bermingham, A.M., M.D.), New York, January, 1884. If, then, as has been shown, the semen does not contain the contagium of syphilis, the male parent cannot transmit it directly to his offspring. The mother must first acquire the disease; and it is only through the disease-germs of syphilis circulating in her organism that the product of conception can be infected before birth. The disease thus acquired, —in accordance with the views of Hutchinson, previously quoted, and in accordance with the views I have advanced, —"subject to the laws of idiosyncrasy, develops equally in all cases."

It is undoubtedly the fact that much disease in fœtal and in infantile life results from pre-existing disease the legitimate sequel of syphilis in the organism of the mother; but that any syphilitic disease proved to be such by its power to transmit syphilis has been communicated to healthy persons, by infants conceived after the active or contagious stage of syphilis in the parents has passed, there is no well-authenticated evidence to prove. And this stage, as has already been stated, has been shown, by ample testimony, not to extend over a period of three or four years.

The pathology and treatment of the late lesions or sequelæ of syphilis will be made the subject of consideration in a subsequent lecture.

G. P. PUTNAM'S SONS will shortly publish, by arrangement with the Vienna publisher, a translation, prepared by Dr. Barney Sachs, with the authorization of the author, of Dr. Meynert's Treatise on Psychiatry. The first part of the work, devoted to the anatomy and physiology of the brain, the publishers hope to have ready by the beginning of the new year. The work will be fully illustrated.

---

ORIGINAL COMMUNICATIONS.

TEN CASES OF EXTRA-GENITAL CHANCRE.

WITH REMARKS.

BY ARTHUR VAN HARLINGEN, M.D.,

Professor of Diseases of the Skin in the Philadelphia Polyclinic.

THE possible occurrence of chancre at other points than about the genitals should always be kept in mind. The statistics of Mauriac and other French observers show that of 3145 chancres 184 were extra-genital, and in private quite as much as in public practice we must be prepared to meet innocent-looking sores, pimples, or abrasions arising no one knows how, and developing into well-marked chancres followed by the general symptoms of syphilis.

It is with the view of drawing attention to the symptoms displayed by certain among the more commonly occurring extra-genital chancres that I have brought together the following cases. They have come under my notice in a practice which is not venereal, but dermatological, and which has included a comparatively small number of cases even of genital chancre, though a large number of syphilitic cases in the later stages come under my observation from one year's end to another.

CASE I.—CHANCRE OF THE LOWER LIP FROM A BITE—DIAGNOSIS OF EPITHELIOMA—EXCISION, FOLLOWED BY GENERAL SYPHILIS.

Elizabeth C., a woman of 52, consulted me on December 12, 1874, suffering with a generalized papular syphilitic eruption which had lasted about three weeks. On making inquiry, I found that three months previously, while toying with a man of suspicious character, she had been bitten upon the lower lip. The sore healed over, and she thought no more of it for several weeks, when a swelling began to show itself in the locality, which enlarged until it became half the size of a hazelnut, when the surface broke down into a running sore. Much alarmed, the patient sought advice of an eminent surgeon, who pronounced the sore a cancer and cut it out. The wound healed over quickly, but within a few weeks a fresh induration made its appearance in the site of the former one, while an eruption began to appear over the body generally. On examination, a small hazel-nut-sized induration was observed under the cicatrix of the operation, together with the general papular eruption noted above. The patient was placed upon appropriate treatment, and the lesion soon disappeared.

The peculiar interest of this case lies in the fact that an eminent surgeon, accustomed to seeing cases of epithelioma of the lip, failed in distinguishing the character of the lesion. The age of the patient certainly pointed to the possibility of epithelioma, while making contagion in amatory converse less likely.

CASE II.—CHANCRE OF THE UPPER AND LOWER LIPS FROM SIMULTANEOUS INOCULATION BY MEANS OF A BITE—TRANSMISSION OF THE DISEASE TO VARIOUS MEMBERS OF THE PATIENT'S FAMILY.

Maggie M., 15 years of age, had connection on November 14, 1876, with a young man whose history is not known, but who showed no signs of disease about the genitalia. She received no injury either to the genitalia or to the mouth at the time, but four weeks later a small sore appeared on the right half of the lower lip. No treatment was employed, and but little change took place in the appearance of the sore for a fortnight, when it seemed to suddenly spring into activity, the lower lip became swollen and raw, and a similar sore made its appearance on the opposing surface of the upper lip. A "lump" also appeared in the throat, and the patient began to experience general malaise, with pains in the bones, etc. About this time she came under the observation of a physician, who failed, however, to make a correct diagnosis, declaring the sores on the lip to be fever-blisters, and the swollen tonsils simple sore throat.

There had been, therefore, practically no treatment employed until the patient came under my notice, on February 28, 1877. At this time she presented well-marked indurated chancres of the upper and lower lip, the enlargement being in each case at least the size of a filbert and covered with a shallow ulcer. The lips were so swollen that they could not be brought together, and there was dribbling of saliva, with difficulty in taking food. The sublingual and submental glands were involved, and there was marked periosteal tenderness over the forehead. Under careful and continuous treatment she entirely recovered, but not before infecting her infant sister, who, in turn, infected her mother and a brother. Thus the entire family, with the exception of one brother, who appears to have escaped infection, contracted syphilis directly or indirectly from this undiagnosticated case of chancre of the lips.

CASE III.—CHANCRE OF THE COMMISSURE OF THE LIPS IN THE HUSBAND—CONTAGION TRANSMITTED LATER IN THE HISTORY OF THE DISEASE TO THE WIFE, PROBABLY BY MUCOUS PATCHES ABOUT THE GENITALIA.

William P., a man of 30, presented himself on March 25, 1878, showing a sore at the left commissure of the lips. This had appeared in the form of a "fever-blister" about two weeks after certain toyings with a prosti-

tute which did not involve connection. It was quite insignificant at first, but was accompanied from the beginning by a glandular swelling under the chin. A few days later the lesion began to enlarge and indurate, while the glandular development became constantly more marked up to the time of his examination. The sore was then in the form of a shallow erosion with a deep fissure extending into the labial commissure, and induration to the size of a cherry. The submental glands were markedly enlarged, although the general swelling was not so great as it had been some days previously.

The patient continued under my care and observation for more than a year, suffering with quite extensive mucous patches about the mouth and anus through the summer. While these lesions were at their height, he had connection with his wife, who consulted me on September 16 for a chancre of the left labium major of several weeks' duration. This ran the usual course, and was followed by a generalized eruption with mucous patches, the woman remaining under my care until April, 1879, when she was discharged cured.

CASE IV.—CHANCRE OF LOWER LIP, FOLLOWED BY MUCOUS PATCHES.

Annie P., 23 years of age, consulted me on December 20, 1880, for a persistent sore occurring upon the lower lip. She was engaged to be married to a man of questionable habits, and was probably infected by him through kissing, the date of which she was able to fix as August 1 previous. The sore was first noticed upon the lip two weeks subsequently. It grew hard and lumpy, and remained in this condition under local treatment until about November 15. Then a generalized eruption of a maculo-papular character appeared, accompanied by general malaise and mucous patches upon the tonsils. When examined, the remains of the initial lesion could still be seen on the lip, accompanied by some induration, and together with this a number of mucous patches on the upper lip and about the mouth. The patient was under treatment about a year, suffering occasional relapses of the mucous patches, but was finally discharged cured.

CASE V.—CHANCRE OF THE UPPER LIP PRESENTING AT FIRST MARKED DIFFICULTY OF DIAGNOSIS, FOLLOWED BY GENERALIZED SYPHILIS.

Kate C., a domestic, 24 years of age, was brought to me on the 7th of last May, by a well-known practitioner of this city, for the purpose of making an exact diagnosis of a suspicious sore upon the upper lip. No history of contagion was obtained. The sore had first appeared as an insignificant abrasion six weeks previously, and had gradually grown to its present size, giving rise to considerable burning sensation at first, but later being quite without feeling.

On examination, a peculiar lesion was found on the centre of the upper lip at the mucocutaneous juncture. This was a firm elevation the size of a ten-cent piece, flat, rising abruptly to the height of an eighth of an inch or more, and seated on a rather firm, inflammatory-looking mass of induration, which could be felt through the tissues of the lip and which was about the size of a small hazelnut. The lesion was of a dusky-red hue, and its surface, abraded and raw in the centre, showed a ring-formed, ill-developed vesicle about the circumference. Just within the lip on the mucous membrane was a lunular shallow herpetic ulcer with a yellowish base. The submaxillary lymphatic glands were markedly enlarged, particularly those on the left side. There were no general symptoms.

The gentleman in whose charge the case had been was inclined, chiefly from circumstantial evidence, to believe that the sore had been contracted by contagion and was syphilitic in character. But, judging simply from the appearances presented, I did not feel prepared to pronounce positively at the first examination, but took the case under advisement. In order to be on the safe side, however, we cauterized the abraded surfaces lightly with nitrate of silver to afford a protective surface, and cautioned the patient against coming into contact with other persons.

She was seen again on the 12th of May, when the sore had already begun to diminish in size and the glands were less swollen. At her third visit, on the 24th of the month, the lesion on the lip was somewhat larger again, being now an indurated lump the size of a split marrow-fat pea, of a pinkish color and without abrasion, while the glandular engorgement under the jaw was decidedly diminished. There were engorged glands in the post-cervical region quite perceptible to the touch, and a generalized sparsely-distributed papular eruption could be seen covering the limbs and neck and to a less degree the body. The mucous membrane of the pharynx was red and congested, but no mucous patches could be found here or anywhere about the mouth. The patient had suffered with severe nocturnal headaches for a week or more previously, coming on after midnight. She had also lost much flesh of late. The patient now confessed that she had frequently of late been exposed to contagion through the mouth from a suspicious quarter, but had never indulged in sexual intercourse.

The chief interest in this case lies in the extreme difficulty of diagnosis. The initial lesion when first seen by me resembled nothing so much as a lesion of herpes iris. The peculiar dusky-pink color, the circinate, partly-developed vesicle, and the evident tendency to spread on the periphery all were strongly in favor of that

affection. It is true that the glandular engorgement was suspicious; but still this, like a bubo in the groin, might have come from a sympathetic irritation due to a simple inflammatory lesion. Here a sure diagnosis seemed impossible until general symptoms developed, but superficial cauterization was practised to establish protection against contagion,—a precautionary measure which I should strongly urge in all cases of the kind.

CASE VI.—CHANCRE OF THE COMMISSURE OF THE LIPS DUE TO A BITE, AND FOLLOWED BY GENERAL SYMPTOMS.

Charles S., 43 years of age, consulted me on August 18 last, suffering from a lump and sore at the left commissure of the lips. His account of himself was that on the 16th of June he had been bitten in the mouth by a prostitute who showed some signs of an eruption about her person. No sexual intercourse had taken place at this time, nor for some months previously.

Within two weeks from the date of this accident the patient began to observe a "pimple" in the left commissure of the lips, which became fissured, and grew in size for several weeks, coming to a stand-still a week or so before I saw him. At that time—two months subsequent to contagion, and six weeks after the appearance of the initial lesion—the patient presented a hickory-nut-sized mass of induration at the left commissure of the lips, at which point was a deep callous fissure extending half an inch inside of the mouth and about a quarter of an inch outside. Within, the buccal mucous membrane showed a silvery-gray roughened eroded patch, while outside a shallow ulcer, the size of a ten-cent piece and of a roundish outline, could be seen on a sharply-defined hard base. Taking the cheek between the thumb and forefinger inside and outside of the mouth, the sharply-defined nodular character of the chancrous induration could be very distinctly felt. The sublingual and submaxillary glands on the affected side could be felt distinctly, although not very markedly enlarged. The post-cervical glands were well marked to the touch. The genitals were closely examined, but showed no sign of disease.

The fissure and erosion within the mouth were touched with dilute solution of nitrate of mercury, while a plaster containing ung. hydrarg. was applied to the external sore. The patient was strenuously warned of the danger of contagion.

Under the local treatment the sores healed over entirely within two weeks, while the indurated lump became lessened in size by nearly one-half. At a visit paid a week after the patient's first appearance I caused him to strip completely, and then found him displaying a well-marked profuse macular eruption, the existence of which I pointed out to him to his great surprise. The patient was then at once placed upon mercurial treatment, and is still under observation, the initial lesion having now almost entirely disappeared.

This series of cases does not include all that have come under my notice. Several others I have refrained from publishing because the evidence of their existence was only circumstantial, although to me convincingly strong. The chief interest in these cases lies, I think, in their comparative frequency, in the simple and innocent manner, so to speak, in which they were contracted, and in the great liability to errors in diagnosis on the part of the practitioner, with possible disaster from contagion to others as the result.

In speaking of these chancres of the lips, Mauriac says that they may occur in any form, minimal, very superficial, epithelial, and erosive, like a patch of herpes, scarcely indurated, and impossible to diagnosticate except for the submaxillary glandular engorgement. On the other hand, they may be very large, and Mauriac speaks of two which were as large as a walnut or a lady-apple, and situated upon the lower lip. Of these varieties only the last is represented in the cases above noted, Case II. being one where the general induration, swelling, and deformity were present to a marked degree. My other cases are of an average character, none, as seen by me, presenting the minimal appearance described by Mauriac. The commoner forms of chancre of the lip are flat or rounded, pseudo-membranous upon the mucous membrane inside of the lip, and crusted when occurring outside on the skin. The slight fissures about the lips, so common in some individuals, are very easily inoculated, and are converted into fissured chancres. The most positive sign that we have to deal with chancre of the lip is the involvement of the submaxillary glands. Occasionally, however, we may meet with this same condition following a simple sore of the mouth. Of course the occurrence of general symptoms will settle the diagnosis, and these, in the form of malaise, headache, lassitude, and loss of flesh, with occasionally pains in the bones and joints, are to be looked for in all suspicious cases which can be kept under observation. The occurrence of a general eruption must, of course, be looked for, and, as this when macular may escape the

patient's observation, it is as well to draw his attention to the possibility of such an occurrence, and to examine the chest, abdomen, and trunk generally from time to time, as well as the more visible parts of the skin, to be sure that a transitory macular rash does not escape notice.

Chancres of the lip are sometimes painful. They are very apt to crack and bleed, particularly when situated in the median line. Considerable tumefaction of the surrounding tissues may take place, especially when the chancre is situated on the lower lip, so that a sort of prolapse of this member may occur, the lip falling out and down on the chin. The induration in these cases is sometimes diffuse, but it is always firmer than simple inflammatory induration, and in the body of it the lesion itself can be felt as a still firmer circumscribed hardening. On the mucous surface of the lips the chancre is nummular, flat, or slightly elevated, and is rarely ulcerated.

The enlargement of the submaxillary glands, which was not very marked in any of my cases, and in some of them was so slight as to escape mention in the notes, occasionally attains considerable proportions and causes a diffuse tumefaction of a part or the whole of the buccal floor. For this reason, patients with their puffy, indurated lips and swollen lower jaw sometimes, at first sight, resemble scrofulous persons.

CASE VII.—CHANCRE OF THE TONGUE, FOLLOWED BY GENERAL SYPHILITIC SYMPTOMS.

Bessie O'S. was one of a group of male and female attendants in a public institution in this city who carried into practice advanced communistic ideas on the subject of syphilitic infection. That which each possessed was shared by all the others. Peter O'C. was under my care with stubborn mucous patches about the tonsils, and later on the commissures of the lips, and about the velum palati and anterior half arches. He was under my observation and care from January to April, 1878. Some time in January the patient conveyed the syphilitic contagion to Mary B., at least so this patient informed me two years and a half later, when she came under my care for late ulcerated lesions of the forearm. When Bessie O'S. consulted me, on February 2, 1878, Peter O'C. was in full tide of syphilis in the mouth. Whether he was the source of her contagion or not I do not know. She told me she had a friend, "Mr. R.," among the attendants, who frequently kissed her, and this friend may have been Peter O'C., or another member of the group. However this may have been, her history was as follows. About December 10, six weeks to two months previously, she observed a small sore near the tip of her tongue, and two weeks later was attacked by a violent sore throat which confined her to bed and which was called diphtheria. From that time until the date of her examination she had failed a good deal in flesh, and when I saw her she looked pale and anæmic to a marked degree. There were no lesions on the body. On the end of the tongue, a little to the left of the tip, could be seen a small roundish ulcer, pin-head-sized, and covered with a gray slough. This was seated upon and surrounded by a mass of induration the size of a large marrow-fat pea split. On touching the lesion with a pointed stick of nitrate of silver, the central slough was wiped away, showing a raw moist surface beneath. The tonsils were swollen, and showed very shallow mucous patches.

Placed upon active treatment, the patient recovered her health, the induration gradually disappeared, but mucous patches kept on recurring during six months. In the autumn the patient returned with a squamous and incipient pustular eruption about the toes, and later new mucous patches appeared in the mouth. She disappeared late in the autumn, still not entirely cured.

I have no comment to make on this case, other than to point out that the lesion on the tongue was evidently the initial lesion of the disease, and that when I saw it it had probably taken on the appearance of a mucous patch, while still retaining the characteristic induration. I regret that my scanty notes give no intimation of the presence or absence of subhyoid or other lymphatic engorgement. This could not have been at all marked.

CASE VIII.—CHANCRE OF THE FACE CONTRACTED IN SHAVING, AND FOLLOWED BY MARKED GENERAL SYMPTOMS OF SYPHILIS.

James F., 53 years of age, consulted me on July 17, 1882, giving the following history. Six weeks previously he had been shaved at a barber's shop of a suspiciously dirty character, in a low quarter of the city, and had been cut in the face just to one side of the chin. Two or three days later, so the patient asserted, a slight enlargement commenced to show itself at the seat of the wound, which increased gradually and progressively in size until, at the time of my examination, it presented itself as a smooth, firm, reddish lump, the size of a hazel-nut, seated in the tissues of the cheek. The surface was unbroken; there was no tendency to ulceration or even abrasion. The submaxillary lymphatic glands

were very much enlarged, and the post-cervical glands also showed considerable engorgement. The suboccipital and supra-trochlear glands were not perceptible.

A few days before I saw the patient his throat had begun to show symptoms of soreness, and on examination a mucous patch could be seen under the tongue, and pain referred to the laryngeal region seemed to indicate the presence of a lesion at that point. A generalized macular eruption was displayed over the body, limbs, and palms of the hands, with a few papular lesions here and there.

The patient was placed upon mercurial treatment, under which the lesions gradually disappeared. He fell away in flesh greatly at first, and became quite emaciated, but gradually recovered, and when last seen, about the end of December, showed no lesions excepting a few mucous patches about disappearing.

Although it is not an uncommon thing to find patients attributing their syphilis to inoculation by means of a razor, yet the actual occurrence under the eye of a chancre due to this method of inoculation is rare. In this case the disease showed itself with more than the average severity, as shown by the unusual emaciation and weakness of the patient. No malignant eruptions (as ulcers, etc.), however, were manifested.

CASE IX.—MAMMARY CHANCRE, FOLLOWED BY LONG-CONTINUED, VARIED, AND REBELLIOUS GENERAL SYMPTOMS.

Elizabeth B., 28 years of age, first came under my care on April 12, 1876. Eight weeks previously, her lover, who she said always suffered with sore mouth and cracked lips, while toying with her bit her left nipple slightly. The trifling wound passed unnoticed for about two weeks, when she observed a small pimple upon the nipple. This soon became larger, moist on the surface, and painful, and the breast became inflamed and hard. Between five and six weeks after the wound of the nipple occurred, a scanty papular eruption made its appearance over the body, and the patient's health began to fail. She suffered malaise, pains in the bones, and general constitutional disturbance. Within a day or two previous to her visit to me the patient began to feel symptoms of sore throat.

On examination, the initial lesion appeared as a semilunar or crescentic ulcer the size of half a dime, situated at the outer border of the areola; the surface, sloping gradually from the edges, which were not raised or everted, showed an eroded cavity covered with yellowish débris and exuding a small quantity of sero-pus. The sore was situated on a base of cartilaginous hardness surrounding it like a ring and raised somewhat above the general surface of the skin. There was a sparse but well-marked papular eruption scattered over the body and limbs.

Placed upon treatment, the initial lesion and the papular eruption gradually disappeared, but a series of mucous patches and the bad condition of the patient's general health necessitated tonic as well as specific treatment continued through a long period. In August, only six months after the initial lesion, a rupial sore appeared upon the leg, and the patient was emaciated and enfeebled, but by the end of the year she seemed entirely well. She was under observation for three years, suffering from gumma of the tongue, serpiginous ulceration over the sole of the foot, etc.

CASE X.—CHANCRE OF THE LOWER EYELID CAUSED BY INOCULATION THROUGH A PUNCTURED CONTUSION—CONFRONTATION WITH THE SOURCE OF THE DISEASE.

As this case shall be reported in full elsewhere, I shall only give the chief points. The lesion occurred in a young man who received a blow below the left eye at the hand of a friend. The immediate tumefaction being considerable, the contusion was punctured with a penknife and sucked by the friend. The sore, a typical erosion on an indurated base, developed in due time, and was seen by me when at its full development. I looked up the friend within a few days, and found him in full tide of florid syphilis, with mucous patches covering the inside of his mouth and the side of his tongue.

I might almost double the number of cases of extra-genital chancre above given if I should include all those which have come under my notice. I have, however, omitted all in which I have not myself seen the initial lesion and followed its evolution so far as to be able to give evidence as to its true nature. My object, as I have already said, has been to point out the daily possibility of the occurrence of chancre of this nature, and to indicate some of its features, and, since I have not intended to write a complete article on the subject, I have not thought desirable to give a list of references. Bumstead and Taylor's well-known work, and the files of the *American Journal of Syphilography and Dermatology* and the *Archives of Dermatology*, afford perhaps the best field for any one desirous of informing himself of the cases of extra-genital chancre reported of late years in English. The French text-books, Fournier and others, with the *Annales de Dermatologie et de Syphiligraphie*, afford a still larger list of cases.

THE EXAMINATION OF APPLICANTS FOR LICENSE TO PRACTISE — A MEANS OF RAISING THE STANDARD OF MEDICAL EDUCATION.

BY EDWARD JACKSON, A.M., M.D.,
Philadelphia.

Read before the American Academy of Medicine at the meeting held in Baltimore, October 28, 1884, *and recommended for publication by the Council.*

THE development of educational institutions may be likened to the development of races of living beings, in that it is determined by what may be called inherent tendencies directed and controlled by external influences. In the case of medical schools, the inherent tendencies reside in the *personnel* of their faculties and the systems of their organization. The external influences, or environment, are to be found in the attitude of the medical profession and the general public towards them and their work, in the bearing of legal enactments upon them, and in the education and desires of the classes from which they have to draw their students. And here, as in the evolution of living beings, environment has full sway over inherent tendencies, fostering such as are in harmony with it, defeating and overcoming those that are not.

Movements for the improvement of medical education have heretofore worked too much on the supposition that the schools could change everything themselves, failing to realize that they are hedged about by influences and bound down by laws of competition against which any effort they may make is practically powerless. I believe that more may be accomplished by so changing the environment of medical schools as to bring it more fully and directly in harmony with all the efforts they may henceforth make to raise their educational standards. As one of several movements tending towards such a change of environment, I ask you to consider the establishment of State boards of medical examiners, whose certificate of fitness should be the only legal qualification for the practice of medicine.

Medical education will only reach a proper standard and properly keep pace with the progress of the time when there is between those engaged in medical teaching a direct and controlling competition to excel in the thoroughness and practical value of the instruction they give. In this country there is now no such direct and controlling competition. Why? In the first place, there is no direct competition because no part of the general public has the opportunity of passing on the merits of more than a few of the schools, and its judgment of them must be based on such knowledge as it can get of the acquirements or deficiencies of a very few of their graduates, perhaps but one or two from each, and these, as is generally understood, may be entirely exceptional among their fellows in the fulness or meagerness of their attainments, the diploma of every American medical school being bestowed on men representative of both the extremes of medical knowledge and medical ignorance. We of the medical profession cannot estimate the goodness or badness of the teaching in the various medical schools of the country, because we have no data upon which to found such an estimate, and the general public, with no more data than we have, are far less able to judge of the matter, if such data were furnished them.

Again, in the absence of direct competition to excel in thoroughness of teaching, such competition as there may be in this direction does not and cannot control the policy of the schools. This is so because most medical teachers are also engaged in other business; and the advantage that accrues to them from medical teaching accrues in other ways than by the reputation for teaching well. In this country the professors control the medical schools. They are unhampered by State control or conditions of endowment, and the board of trustees exists rather as a figure-head or a technicality. And in every faculty, if there be any who look to medical teaching to furnish the larger part of their income, or who base upon it their hopes of fame, they constitute an insignificant minority. To the large majority of teachers the chief rewards of medical teaching are the opportunities it offers for the enlargement of practice and the attainment of fees, or material for original research. The professorship is a certificate given by the board of trustees, but representing the judgment of the medical faculty, that its holder is eminent in a certain particular department of medicine; a certificate that is advertised to the profession and to the general public in the published circulars and announcements of the school,

and by appended title, and by word of mouth. It is a certificate worth having. Then, again, simply to stand in the relation of teacher to young men, many of whom will go out to take prominent positions in the community, is to have an opportunity for achieving reputation and attracting clients that is almost unequalled.

It is, perhaps, not accurate to say that we have no data upon which to grade the different medical schools of the country. There is one way, and only one, in which we might, or the general public might, arrange them; they might be arranged according to the size of their classes. By that, and only by that, can we judge of the success they achieve, and inferentially of the success they deserve. So, whether the medical teacher finds the chief advantage of his position in the fees he receives for teaching, in the opportunities for practice that his teaching opens up to him, in the material it brings him for original research, or in the reputation and influence that come from the teaching itself, the extent of that advantage is measured by the number of students he teaches.

The existent competition is for large numbers of students, and to secure them the first attraction that the schools have to offer is the degree of Doctor of Medicine. This degree has been borne by many great men; it has become, in this country, the badge of membership in a so-called liberal profession; but a more weighty consideration than these is the fact that it is required by public opinion, and in some States by statute law, as a prerequisite to entering upon the business of medical practice. As matters now stand, medical schools use this degree not to honor themselves in the eminence of those upon whom it is bestowed, not to guarantee to the public the professional fitness of those who bear it, but as a bait to draw students. And it draws the student not by the honor which once clothed it, but has now departed, but because in the present state of public opinion and statute law he must have the degree before he can undertake, with any fair prospect of success, to make a living by the practice of medicine.

The other means by which a school attracts students need not be dwelt upon. Suffice it to remind you that chief among them is the reputation of individual members of its faculty as compilers, original investigators, or practitioners, not as teachers.

Then come the boasted attractions of museums, libraries, and clinical facilities, that make a fine display, but which are of little value to the student until he has considerably advanced in his acquirements, —farther, indeed, than many get before graduation. After these come free scholarships, cheap boarding, etc.; but on the list of attractions, strictness in the requirements for graduation comes last, or more generally is omitted entirely.

Now, it seems to me that the change most urgently needed in the influences bearing upon medical schools from without is that which will deprive the degree furnished by the schools of its purely trade value as a preliminary to money-getting, and will substitute for it a certificate of the attainment of a certain minimum standard of knowledge of the arts and sciences of medicine, given by a board of disinterested examiners acquainted with those arts and sciences and with the needs of the community. The creation of such a tribunal, furnished, in the persons of medical graduates of various schools, with the needful data, and competent and interested to pass impartially upon the thoroughness of the teaching those graduates have received, would establish that direct competition for thoroughness that is so much needed, and would go far towards giving such competition a controlling influence. If the relegation of the medical degree to its proper place as a scholastic honor pure and simple did not induce the schools to sufficiently respect their reputations in conferring it, the publication of the fact by the rejection of their graduates would certainly have the desired effect.

Other sufficient reasons for the establishment of State boards of medical examiners could be discussed, but it is only the influence which they might exert over medical education that I would urge here, and from the point of view that such an influence is one of their most valuable and important functions, I wish to say a few things as to their constitution and how they should go about their work. Their work is not to confer medical honors; it is simply to protect the public from gross ignorance in its medical advisers, and incidentally to remove from medical schools the temptation to swell their classes by the pretended education of men unfit to acquire a knowledge of medicine.

I believe that it would be entirely prac-

ticable, and in many respects it would be most advantageous, to have but a single examining board in each State. The responsibility would then be undivided. Its doings would attract more general attention than would the work of a number of boards, each of but local importance. It might, from time to time, hold examinations in various parts of the State, if that were considered necessary; but certainly the fairness of the test and the weight of the verdict would be greater to have all applicants go before a single board.

That no law can be secured or enforced which does not take cognizance of certain dogmas or so-called schools of therapeutics is certainly true of many parts of the country, and this constitutes one of the serious obstacles to any such progress as we are hoping for. My own preference would be, that it should be met by not examining with reference to therapeutics through the agency of drugs, since, even aside from exclusive dogmas, but few lines of drug treatment are entirely agreed upon by the regular profession, and it would be impossible to examine applicants with fairness upon matters of individual preference and opinion. Probably, however, a more popular way would be to hold such examinations, and to provide for the so-called schools of medicine by giving homœopathists and eclectics representatives in the boards, with authority to pass, on that particular branch, such applicants as might desire to be examined by them. I see no very serious objection to some such plan, since the unity of the healing art would be sufficiently vindicated by the single examination on all other branches.

The examiners should receive a fixed compensation, in no way dependent upon the number of applicants examined or passed by them. The superiority this alone would give the State board over the faculty of the medical school need not be dwelt upon. For similar reasons, the examiners should not be involved in the business of medical teaching; neither should they be chosen by those engaged in teaching, but rather by bodies representative of the profession, as the State medical societies, or by the representatives of the whole people, the governors or legislatures of the States.

The examiners should have long official terms, which should not expire simultaneously, such a provision being necessary to secure stability and continuity in the policy of the board.

The examinations should, as far as possible, be written, for written examinations, besides being most easily made fair, uniform, and thorough, can be matters of record. But above all they should be practical.

In conclusion, let me reiterate my most earnest belief that such State boards should have for their function the examination of applicants for the license to practise, and not the endorsing of the diplomas of certain medical schools, for the public is more abused by the disparity in the attainments of men receiving their degrees from the same faculty than by any disparity existing between the requirements of the different schools that lay any claim to respectability. Such boards might have their sphere of usefulness increased by power to conduct or supervise examinations in the branches of learning that fit men to become students of medicine, but this, and the right to be influenced by considerations of moral fitness or unfitness of the candidate, should be the only extension of their powers. Let them attend to their principal duty, without hinderance from diverse and distracting interests and responsibilities.

REPORT ON THE PROGRESS OF OTOLOGY.

BY CHARLES H. BURNETT, M.D.,
Philadelphia.

(Continued from page 43.)

NEURALGIA, CHIEFLY IN THE TRACT OF THE SECOND BRANCH OF THE TRIGEMINUS, CAUSED BY AN EXOSTOSIS IN THE EXTERNAL AUDITORY CANAL.

POLITZER gives a *résumé* of an article on this subject by Moos in the *Annales des Maladies de l' Oreille, du Larynx*, etc., May, 1884.

The patient, in this instance, complained originally of an abscess in the ear, followed by a purulent discharge. In March, 1883, there occurred a painful swelling of the right external auditory canal, soon followed by attacks of violent pain, occurring sometimes in the morning and sometimes in the evening,—at first at long intervals, but finally more frequently and with increasing intensity. These pains affected

chiefly the region of the second and third branches of the trifacial nerve. The right jaw especially became so sensitive in chewing that finally the patient chewed only on the left side.

Examination of the ear revealed in the right external auditory canal three exostoses about as large as a pea, situated on the posterior, the superior, and the anterior walls respectively. These were nearly in the same plane and very close to one another. Upon touching these with a probe, the patient was positive that from the hindmost of them the attacks of pain took their origin. On the 9th of July, 1883, Prof. Moos removed the posterior exostosis by means of two incisions with a small bistoury. The superior one was left intact. The anterior exostosis was incised. After the bleeding ceased, the external auditory canal was plugged with boric acid and salicylated cotton-wool. Immediately after the operation the pains ceased, and have not returned, and on the same day, for the first time in many months, the patient was able to chew upon the right side of his mouth. Subsequently some granulations sprang up, and there was a purulent discharge, which, however, soon diminished and finally ceased entirely during a course of baths at Ragatz.

The original cause of the formation of the exostoses was probably a chronic purulent inflammation. It is very certain that at the seat of their development there occurred a tension and a torsion of one of the branches of the trigeminus, to which can be attributed the painful paroxysms of the disease.

THE TREATMENT OF SUPPURATIVE OTITIS MEDIA.

Bürkner (*Berlin. Klin. Wochenschrift*, No. 1, 1884) holds that, in addition to nitrate of silver in strong solutions (Schwartze) and powdered boric acid (Bezold), a valuable remedy for suppurative otorrhœa is found in corrosive sublimate and in the red precipitate of mercury. He has employed corrosive sublimate in two forms,—viz., by injections, and by instillations into the auditory canal. For injections he advises the one-per-cent. solutions of the sublimate, employing them in cases of fetid and abundant suppurations of the middle ear. For general use, however, he prefers warm instillations in the form of aqueous or alcoholic solutions 0.05 in strength. The use of more concentrated solutions has not been found painful. The effects of the sublimate are said to be remarkable in chronic cases, which nitrate of silver and boric acid have entirely failed to cure. The author has used the solutions of the sublimate in cases with small or with large perforations, and in both acute and chronic cases, and has cured at least half his cases,—no very great success, after all, in the estimation of your reporter, since the statistics of the dry, antiseptic treatments are far better, being from eighty to ninety per cent. of cures.

The red precipitate of mercury, on account of its insolubility, can be used only in a limited number of cases with advantage. It can be used only as a powder, and in small quantities, in cases of slight purulent secretion, with large perforations in the membrana tympani, since, like alum, it forms hard curds with the mucous secretions. In cases of hypertrophy of the mucous membrane of the tympanic cavity, and in granulations of the membrana tympani (myringitis chronica), the red precipitate, it is claimed by the author, produces far better results than boric acid. It is not to be used except in cases of extensive perforation, and not in combination with the boric acid or dry treatment of the ear.

DILUTE SULPHUROUS ACID IN LIMITED CARIES OF THE FUNDUS OF THE AUDITORY CANAL.

In this connection, a suggestion of Woakes, of London, deserves a notice. In the *Annales des Maladies de l' Oreille*, etc., July, 1884, Dr. Woakes recommends the use of dilute sulphurous acid (B. P. nine per cent.) in cases where limited caries, either in the fundus of the canal, near the membrana tympani, or in the tympanic cavity, can be detected by the use of a probe. It is claimed by this author that when the fundus of an ear which has long been the seat of an obstinate otorrhœa is examined under good illumination, there will usually be found a spot of granulation-tissue seated either upon the membrana tympani or very near its periphery, on the wall of the auditory canal.

Such a granulation on the membrana marks the position of a perforation in it, the proliferating tissue proceeding from the mucous lining of the middle ear. If,

now, such a granulation mass be penetrated to its base with a fine probe, a slight grating sound will be perceived, indicating the presence of exposed bone. This, of course, demonstrates the existence of a limited caries or necrosis on the osseous walls of the drum-cavity. "Reference is not made in this statement to those gross cases of disease of the temporal bone, the nature of which is quite obvious to the casual observer, but rather to occurrences which may complicate, while they directly result from, an ordinary middle-ear catarrh, and which will assuredly not be recognized unless specially sought for in the manner above described."

To combat this condition, sulphurous acid (B. P.) diluted with three or more parts of water, according to the requirements of the case, has been used for the past five years, with general satisfaction. "If, as rarely happens, the external canal resents its presence and shows signs of irritation, the strength of the solution must be lowered, or its use discontinued for a time." The rationale of its action appears to be that when maintained in contact with the carious surface the dilute acid dissolves the earthy salts of the minute spicules of dead bone which project from the carious surface. It also removes the discharge from and disinfects the surface producing the necrotic spicules, and by its stimulating influence induces a healthy action, which rapidly ends in cicatrization.

The application of the dilute sulphurous acid is to be used only when exposed bone is felt in the fundus of the canal by means of a probe. The instillations are to be made warm, thrice daily, and allowed to remain half an hour *in situ*, the patient being in a suitable lying posture. In four or five weeks a cure can generally be effected. Prior removal of granulation-tissue is not necessary, except where its bulk prevents or retards the access of the acid to the underlying caries.

LARGE DOSES OF POTASSIUM OR SODIUM IODIDE IN SUDDEN DEAFNESS OF SUPPOSED SYPHILITIC ORIGIN.

Dr. Albert H. Buck, of New York (*New York Medical Record*, September 6, 1884), offers a series of brief histories of cases as a contribution to the subject of the daily administration, through a period of several days or weeks, of large doses of potassium or sodium iodide for the relief of sudden or rapidly-developed deafness, due apparently to the presence of syphilitic lesions in the labyrinth, or in some part of the auditory nerve outside of this system of cavities, or, finally, in those parts of the tympanum which constitute the movable barriers of separation between this cavity and those of the labyrinth. The chief object of this communication is to throw a little light, if possible, upon the prognosis and treatment of what appears to be syphilitic disease of the labyrinth, and to induce others to communicate their experience in the treatment of such cases. All cases of syphilitic diseases of the middle ear are excluded from consideration. Those cases are chosen for study in which the profoundness of the deafness and the rapid manner in which it develops seem characteristic of syphilitic disease of the auditory nerve, rather than of catarrhal lesions in the tympanum.

Dr. Buck regards those conditions of total deafness which have been attributed to syphilitic disease of the labyrinth, and which have been reported by some observers as entirely cured in a few weeks by specific treatment, as probably not due to lesions in the labyrinth, as "it is not perfectly clear that middle-ear lesions may not have contributed materially to the deafness."

Accounts of five cases are then given, in the first of which, a man, 38 years old, ordinary anti-syphilitic treatment was carried out without any improvement in the hearing. In the second case, a man, 27 years old, the anti-syphilitic treatment at first consisted in daily inunctions of a five-per cent. preparation of Squibb's oleate of mercury, and the internal administration of the iodide of potassium three times daily, in increasing doses. The iodide of potassium was continued for six months, until the patient took five hundred and twenty-five grains daily. Profound constitutional effects were thus produced, but no improvement in hearing.

The drug was administered in all the cases according to the suggestion of Dr. F. R. Sturgis, of New York, in a saturated solution, so that one minim equalled one grain.

In the third case, a man, 45 years old, in the course of three months the administration of the drug was carried to three hundred and fifteen grains daily, and kept up two weeks, *without any unpleasant effects*, but also without any appreciable improve-

ment in the condition of the hearing. The treatment was then abandoned.

In a fourth case, a man, 52 years old, in whom, however, the syphilitic origin of the deafness was not entirely clear to Dr. Buck's mind, thirty grains of the iodide of sodium was given daily at first, and then increased, until in the course of a month for six days the patient took three hundred and sixty grains daily.

The hearing, however, was not restored in the slightest degree, and the tinnitus was not appreciably diminished. Treatment was then abandoned.

In the fifth case, a man, 40 years old, two days before seen by Dr. Buck, there had been decided vertigo, nausea, and double tinnitus; in a short time vomiting of mucus and bile at intervals for several hours. It was then discovered by the patient that he had lost the hearing of both ears. Examination of the ears revealed no lesions other than those of chronic catarrhal inflammation of both tympana. As the patient had been under Dr. Buck's care ten years before for syphilitic sore throat and with subacute otitis media, the mixed treatment just described was tried in this case. In four days the vertigo had nearly ceased, and the patient could hear a loud voice. In the course of a month it was learned that little or no improvement had taken place in his hearing, and that the tinnitus was still marked. Up to this time he had been able to take only ninety grains of iodide of potassium daily. The iodide of sodium could not be taken, as it nauseated him. In the course of a week the quantity of iodide of potassium was increased to one hundred and eighty grains, but this was soon abandoned, as the patient's stomach rebelled. Finally, this man took two hundred and seventy grains daily, but in a week it was abandoned, as it seemed to do him more harm than good. It certainly produced little or no effect upon the hearing, as he had to be communicated with by writing.

In conclusion, Dr. Buck says, "The treatment failed to accomplish anything worthy the name of improvement in all five instances, and yet, as has been observed in the cases reported by Dr. Roosa and Dr. Webster, essentially the same treatment may accomplish strikingly favorable results. . . . The only plausible explanation that I can give of the infrequency of our successes is this: A syphilitic gumma in the labyrinth, and especially in the cochlea, will rarely fail to produce damage from which recovery is scarcely possible. Treatment may lead to the absorption of the gumma, but it cannot readjust and render functionally useful those delicate and carefully-adjusted organs which the tumor has disarranged, and perhaps even destroyed. . . . In the cases reported by Drs. Roosa and Webster we may assume that the pressure had gone only so far as to suspend for a time the vibratory power of the cochlear structures, but had not destroyed or even seriously injured them. It is also possible that the gumma may occupy a position in the vicinity of the oval window and foot-plate of the stirrup, or in that of the secondary tympanic membrane (round window). A lesion so situated would be competent to annul the power of hearing, but it would not necessarily destroy it," which is essentially the view of the subject expressed by your reporter in No. 414 of this journal (October 6, 1883).

TRANSLATIONS.

THE FUNCTIONAL INDEPENDENCE OF THE TWO CEREBRAL HEMISPHERES—ITS DEMONSTRATION BY EXPERIMENTAL HYPNOTISM.—In a recent Paris thesis M. Berillon gives the results of researches into the physiological, independent activity of function possessed by the cerebral hemispheres, and quotes in confirmation of this view evidence from anatomy, physiology, embryogeny, cerebral thermometry, comparative pathology, human pathology, mental pathology, psychological observation, and more directly from experimental hypnotism. By following this path of investigation, which Charcot and Dumontpallier have enlightened by so much patient and laborious investigation, M. Berillon believes that he has succeeded in demonstrating in a manner almost irrefutable the duality of the cerebrum and the functional independence of the two cerebral hemispheres.

From experiments upon patients at La Pitié it was shown that hypnotism (1) may be localized in one hemisphere; (2) may be exercised simultaneously in the two hemispheres, although in different degree. Without stopping to consider the means of inducing unilateral or bilateral

cerebral hypnosis (further than to indicate that the condition was established by excluding one of the eyes by means of a bandage, and by thus acting upon only one retina or upon both in succession), we will give the conclusions contained in a *résumé* of the investigations of the author. The work is in two parts.

"In the first part are grouped methodically a large number of facts taken from divers branches of biological science, which appear susceptible of contributing proof to the theory of the functional independence of the two cerebral hemispheres. These facts are already known, and result equally from experiments and observation upon animals, and observation upon man.

"In the second part of the work there appear, on the contrary, a great number of facts entirely new, which in this case offer the special interest of being the result of experimentation directly upon man. These experiments are due to a mode of physiological investigation which is still seldom applied,—experimental hypnotism. By this it can be proved that in the human subject, by pursuing certain methods and at the will of the experimenter, we can

"(1) Suppress the psychic motor and sensory activity of one cerebral hemisphere (unilateral cerebral hypnotism).

"(2) Give to each hemisphere a different degree of activity (bilateral cerebral hypnotism, of different degree for each side).

"(3) The two hemispheres having equal activity, to create for each of them and simultaneously the manifestations of hypnotism of different nature and character (bilateral cerebral hypnotism of similar degree, but with different manifestations for each side)."

Referring to the latter form, the author explains this curious condition as follows: "That is to say, that the same individual can, in a hypnotic state, represent by each of his hemispheres a *distinct being* endowed with an individuality of its own. In such a condition, each hemisphere being complete by itself (although its action may be generally, from a stand-point of motility, limited to a single side of the body), and possessing within the limits of its attributes a special activity, one might say that man, whether from a psychic, sensory, or motor point of view, is really double; *in short, that he possesses two organs of ideation,—two brains.*

It would be impossible, the author says, in conclusion, to demonstrate experimentally upon man, in a more striking or precise manner, the *cerebral duality* and the functional independence of the two cerebral hemispheres, than he has done by this novel method of experimentation.—*La France Médicale.*

ASEPTOL.—A phenol compound, termed orthoxyphenylsulphurous acid, has been recently introduced into therapeutics under the name of "aseptol," this title having been given to it on account of its remarkable germicide qualities, which excel those of carbolic and salicylic acids. Aseptol is an amber-colored fluid, of a density 1400; it has a slight odor, but is more pleasant to the smell and is less poisonous than carbolic acid. Last November Drs. Leroy and Van den Shrieck, of Antwerp, studied the therapeutic applications of aseptol, and reported most satisfactory results as an antiseptic. It has the following advantages over antiseptics in common use:

1. It is very soluble in water.
2. It is very slightly caustic.
3. It is free from irritative qualities, and may be applied for a long time to the skin, the eyes, the bladder, etc.
4. Finally, its slight toxicity, which permits its use internally in considerable doses, and also the application of concentrated solutions in diphtheritic pharyngitis and laryngitis.—*La France Médicale.*

HYDROCHLORATE OF COCOAINE, THE NEW LOCAL ANÆSTHETIC.—Upon the recommendation of Dr. Koller, of Vienna, the muriate of cocoaine has been used with surprising results as a local anæsthetic in ophthalmic surgery. Dr. Noyes having written a letter containing an account of the Heidelberg Ophthalmological Congress to the *Medical Record*, in which he described its almost magical effect, it has been tried by a number of New York surgeons. Drs. Knapp, Agnew, More, and Minor have performed a number of operations with its aid, using a two-per-cent solution of the drug (Merck's). Two drops at a time instilled into the eye to be operated upon for squint, for cataract, or for enucleation, repeated every five minutes, brought about such insensibility of the eye that no other anæsthetic was needed, and even in children painful operations were done without any suffering whatever. One of the experimenters declares that, "should cocoaine in the hands of others meet with the same success that I have attained, it will mark an era in ophthalmology unsurpassed by any in modern times. Its use in other branches of medicine and surgery may be almost as important as in ophthalmology."

EDITORIAL.

STATE EXAMINING BOARDS.

HE who has sown seed amidst derision because of its alleged want of vitality and the apparent poorness of the soil may well watch with pleasurable pride and self-congratulation the growing grain as it ripens for the harvest. It is thus we note that the State Medical Society, the Philadelphia County Medical Society, and the Philadelphia Medico-Legal Society have appointed committees to secure the passage of a law providing that no person shall, after its enactment, enter the practice of medicine in Pennsylvania save only by passing a medical examination before a State Board of Examiners. A valuable essay, in advocacy of this view, we gladly publish upon another page.

Many years since, we stated in these pages our earnest opinion that such a law as this should be adopted; and we see no necessity for here reiterating the reasons then assigned. We believe that the medical profession of the State are now persuaded that such a measure is needed for their own protection, as well as for securing the people against the ravages of uneducated practitioners. The discussion is no longer, Ought this thing to be done? but, How shall it be accomplished?

If the three committees are in thorough earnest, they can secure the passage of the law at the next session of the Legislature.

From whence cometh the opposition? Only is it to be expected from the medical schools; and these can hardly afford to act openly against the proposed law. Institutions with graded courses and strict examinations will naturally welcome such law, as making plain their superiority, and other schools can scarcely proclaim with advantage their belief in their own insufficiency and weakness.

It is all-important that the law be carefully drafted, and it is plain, to our thinking, that certain principles should be involved in it. In the first place, there should be but one board in the State,—at least one for each "school" of medicine: otherwise there could not well be persistent uniformity of action: every board would be thinking of itself in comparison with another, and be very prone to guide its examinations, not by a simple sense of right, but, at least in part, by what its neighbor was doing. Moreover, one central board would be more dominated by a sense of responsibility, and more free from local feelings, than would local committees. It is no great hardship for the man who desires to enter practice to travel even the whole length of the State in order to obtain this privilege. Moreover, if the sessions were held in Philadelphia, as most of the candidates graduate in this city, they would be here ready for examination in the spring.

Another principle which should be clearly recognized is that the examinations should, entirely or in great part, be matters of record, and therefore be in writing, the examination-papers to be preserved for at least ten years, and the written questions to be published at the close of the examination. As some rejected candidates might not want their blunders preserved, they should have the right to withdraw their papers after signing a written acquiescence in the justness of their rejection.

A second important principle is the recognition of the ugly fact that there are several schools of therapeutics,—or schools of real and imaginary therapeutics, if exactly accurate phraseology be preferred. The difficulty can readily be overcome in one of several ways: (1) by having two examiners in therapeutics, and the candidate not to state which of them he should

choose until he had passed the rest of the board; (2) by having no examiner in therapeutics; (3) by having various examining boards, one for each so-called sect in medicine. According to our present thought, the latter would be the best plan: there would be no mixing of the regular and irregular professions; there would be no possibility of complaints by candidates of prejudices against them on the part of examiners other than the therapeutists, because of the candidates' therapeutic predilections; there would be no jealousy and no struggle between sects concerning positions upon the board other than that of the therapeutist. We believe it would be best for all concerned to allow every *incorporated* State Medical Society to give a list of names to the Governor of the State, out of which he should appoint an examining board, who should license to practise in accordance with the rules of said society. The objection, of course, is that the inferior sects of practitioners would appoint inferior boards and open the doors wide to applicants. If, however, the examination-papers were accessible to every one, this evil would not, we think, be uncurbed, and, at any rate, the regular profession might maintain its own dignity. The State Board of Health, when created, or some other body, might have the duty laid upon it of reporting on the examination-papers at intervals.

A LESSON FROM THE ELECTRICAL EXHIBITION.

THE Electrical Exhibition of the Franklin Institute of this city has closed, after a very successful run,—as the dramatic critic would say,—and the various committees of judges have about finished their tasks, though, in some cases, still very actively at work. The display of medical electrical apparatus was distinctly inferior to what might have been expected, several of the largest manufacturing houses in America not being represented. But there are a few conclusions to be drawn or facts stated that seem worthy of note here. The old, well-known story of the powerful current setting towards quackery in all things electrical was most marked. There were but two, or possibly three, honest electro-therapeutical exhibitions in the whole list. The medical profession is in part to blame for this, because many physicians use batteries sold under false claims, and even a goodly number of practitioners do not know that such claims are false.

Every battery which is offered, as many of them are, as giving a galvanic current from the primary faradic coil, is fraudulent in at least this claim. The faradic current is induced only at the making and the breaking of the circuit. When the circuit is closed, the galvanic current, of course, passes through the closed circuit and does not enter the body; when the circuit is opened, of course the galvanic current cannot pass anywhere, because there can be no current, it being the cessation (*i.e.*, breaking) of the current which makes the induction. It is plain that a force cannot be existent and non-existent at the same time, any more than can a material substance. If the galvanic current exists and is not interrupted or broken, there can be no induction.

Again, faradic batteries which profess to get divers mysteriously-endowed currents by using a multiplicity of coils made of wires of different sizes or of different metals, methods of winding, etc., are fraudulent in their claims. There is but one kind of galvanism, and currents can only vary in strength and electro-motive force. Alongside of the highly scientific batteries, dynamos, and what not of the exhibition were medical batteries asserting practically that there is such a thing as a copper electricity, an iron electricity, a silver electricity, and so on. All of which reminds one of certain parts of London, in which the lowest slums abut against the fine palaces of the money-kings.

One word more concerning faradic batteries is all that is here necessary. No physician should buy a faradic battery which is not provided with a slow rheotome or current-interruptor, and this ought to be so constructed that it can be adjusted to run at the rate of sixty per minute, or with a swiftness approximate to the slowest beat of the rapid rheotome. On only two faradic batteries at the Exhibition were such rheotomes.

Most of the portable galvanic or chemical batteries which were exhibited are modifications of the old Stohrer battery, and are open to very serious objections. The liquid is a solution of the bichromate of potassium in diluted sulphuric acid, and is excessively corrosive. The connections are very close to the liquid, and therefore very prone to become corroded. The closeness of the cells is such that the joints are exceedingly apt to get loose with use and to allow of leakage. When it is further remembered that this form of cell is one of the most rapidly polarized and exhausted of any known, it can be well seen that a portable galvanic battery for practical use is, so far as the exhibits alluded to are concerned, still a desideratum.

There were two portable galvanic batteries shown at the Exhibition which are not widely known, but which are the most promising forms we have ever seen. One of these, exhibited by Mr. Otto Flemming, has modified Leclanché elements. The electro-motive force of these elements is not nearly so good as is that of a freshly-charged bichromate battery, but in permanence and regularity of action and in freedom from corrosive properties they are almost unrivalled. With a change in the mechanical arrangement, so that the cells could be more permanently closed, this battery might prove to be thoroughly adapted to our wants.

Another form of galvanic battery having remarkable electro-motive force, and therefore especially adapted to medical use, is that invented by Mr. Partz. The plates in this battery are of carbon and zinc, as in the ordinary sulpho-bichromate-of-potash cell, but the fluid is a solution of chloride of zinc and bichromate of ammonium. The inventor claims that this form of element has an electro-motive force nearly equal to that of a Grenet cell, whilst polarization takes place so slowly as to be practically non-existent for medical purposes, and exhaustion of the fluid is so slight that a battery will do a year of ordinary medical work without replenishing. A very important feature is that there is no "local action" in the battery, and that, consequently, immersion of the plates does not have any effect upon them or the fluid, so long as the circuit is not closed. As a result of this, the cells can be made perfectly tight and at the same time be kept small. There is therefore no danger of leakage during transportation, and the weight of a charged battery of fifteen cells is only fourteen pounds.

Both the portable Leclanché battery of Mr. Flemming and the Partz battery were referred to the committee of judges, for report upon their electro-motive force and upon their "rate of fall,"—*i.e.*, loss of power during use. Until such report is made public we may well suspend judgment, but it does look as though we might expect in one or both of them a solution of the problem how to make a practical portable galvanic battery for medical use.

ONE of the most important duties performed by the International Medical Congress held at Copenhagen was the passage of a resolution creating an International Committee for the Collective Investigation of Disease. Professors Jacobi, of New York, and N. S. Davis, of Chicago, were appointed as representatives in the United States. It is to be hoped that the general profession will aid the committee, in order that satisfactory progress may be shown at the meeting of the International Congress at Washington.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THE winter session of 1884–85 has now commenced, and at many of the metropolitan schools the old custom is observed of giving an address to the students, old and new. Some schools have abandoned the address in favor of a conversazione; but which really impresses the student most is a matter on which opinions may and legitimately can differ. When the reasons why a man is chosen or adopted as one of the lecturing staff of a medical school are known and understood, and his power of exposition has a known value, then it might be possible to make the worth of the introductory address a matter of calculation. However that may be, the addresses of the present year have not fallen behind their predecessors. That at University College was delivered by Dr. W. R. Gowers, one of the physicians of the hospital, a man who has done good work, and who holds a good position as one likely to uphold the reputation which University College has deservedly won. He first welcomed the new-comers, and then pointed out the wide range of information which is required for a medical man. It is not merely the scope of the examination-questions, entailing some acquaintance with about half the sciences, but the requirements of practice, which touch nearly every branch of science. "The life-work of the medical man," he said, "was the prevention, cure, and alleviation of the diseases of man. Whatever else man is, he is part of the material world, and is, moreover, the highest and most complete phenomenon yet discovered, or likely to be discovered,—that in which the interactions of force attain the highest elaboration known to us. The most complete form of matter, the most delicate adjustment of force, is presented by a nerve-cell of the brain. Of the slow, never-resting tide of creature-development, sweeping on through ages far behind us, ebbing and flowing, and yet, with sure advance, moulding into new forms and higher phases the mysterious elements on which it works, the ultimate result, the highest issue, is the subject of your study." This was a tolerably stiff bit of evolution for the freshmen; but, then, breadth of view and untrammelled thought are known to obtain at the college in Gower Street. He continued, "But elevation entails instability. The exquisite capacities of organic bodies are obtained by a delicate adjustment of restrained energy, ever striving to gain some lower and more stable state, held in an equilibrium that is destroyed by the slightest change, and is, indeed, in constant process of destruction and renewal. Hence, by altered constitution and function, a living organism responds to every variation in the conditions outside it,—to every change in temperature, mechanical forces, chemical constitution, of its surroundings, and doubtless, though more obscurely, to every alteration in electrical and, perhaps, magnetic states. To every change in earth and air the human frame is sensitive. Each motion of our rolling world, each wave of light from the far-off sun, each wind that bears to us the warmth of tropic seas or cold of mountain snows, determines some change in us. An alteration of the soil on which we live may modify completely the processes of life." Consequently the medical man, in order to cope successfully with the disturbances within the organism set up by such a myriad of causes, must have far-reaching, wide, almost all-embracing information to deal with the causes which are producing the results; and a tolerably trying outlook for the juvenile mental powers he sketched. Though, of course, what he said is quite true. And those youngsters, when they become gray-haired and skilled practitioners, will have learned the multitude of varied causes which lead to a yellow-furred tongue, telling of disorder of the liver, from causes varying from the east wind to a business complication entailing worry. But in the mean time we hope that they will learn to give a dose of calomel and a few grains of jalap, when such evidences of liver-disturbance are present, until they can deal with the causal relations of it. When they can calculate these, then probably they can do away with the necessity for the mercurial cholagogue and purgative.

Having, then, pointed out the object of the various subjects of study required in a medical curriculum, he passed on to a very important matter (on which, indeed, an address on the termination of a college career would not be out of place), and that was the importance of entering into the feelings and thoughts of sick persons, so as to deal with them with proper consideration. To enter fully and deeply into suffering with the sympathy that is not only intelligent, but "with suffering," he admitted was "impossible. A doctor's work would then be simply beyond human endurance. To him, as to no other, the darkest side of human nature is ever open; in his ears the deep undertone of sadness rings through every chord and melody of life,—now in the wail of pure distress, now in the discords of passion, now rising into the sweet but still, sad music of patient resignation and of self-sacrificing love. Well it is for the world that it is possible to understand without enduring, or the helpers would be few. As it is, our lives are often saddened by the suffering we cannot but share. No statement more untrue was ever uttered than that familiarity with suffering destroys the capacity for sympathy in medical men. It is one of the many statements that are made

regarding the members of the medical profession—misconceptions of their feelings and their motives—which could not be made if the character of the profession as a whole and the value of its work were duly appreciated." Here Dr. Gowers spoke up for a much maligned profession in a manner becoming his position. After that he went into some detail as to the actual amount of good done by the profession in a single year. He pointed out how active was the part taken by the profession in the prevention of disease, and stated that no other members of the community strove so hard to deprive themselves of at least half their living. How far, by our present capacity to rear delicate children, the profession was providing itself with work in the future was a matter lightly and cautiously touched upon. He then had a few words to say about the rewards of our profession, which, he pointed out, were other than pecuniary; for of the last it would reap but little. Nor did he say much of honors granted to it.

At St. Thomas's Hospital the address was given by Sir Risdon Bennett, consulting physician to the institution and an ex-president of the College of Physicians. He also took the line of the wide information required by a medical practitioner, including psychology: "It needs but a slight acquaintance with the practice of medicine to learn how greatly the equilibrium of health depends on the due regulation of psychical as well as physical force." Indeed, he thought psychology belonged quite as much to medicine as to those who devoted themselves to psychiatrics. Disease in its manifestations was modified in several ways by mental states. He remarked that "At the bedside the practitioner has to do with something that cannot be studied in the dissecting-room,"—which was certainly true; and he might have stated, equally truthfully, nor in the pathological room either. It will be long ere the microscope can demonstrate in a brain-cell a life of self-devotion to others, or even the effects of an overmastering ambition. Then he referred to the wide domain of therapeutics, and showed how hygiene, diet, and regimen were a part thereof. Indeed, he had a word to say in favor of an acquaintance with cookery. He said, also, with the wisdom born of long experience, "Whatever the genius of some, or the special opportunities of others, may enable them to expect, it is by close observation of nature—which all may and are bound to cultivate—that most of us can hope to attain what should be the desire of all;" and then concluded with some quotations from Sir Thomas Browne, which apply as well now as when first uttered.

At Westminster, Dr. A. Hughes Bennett, the respected son of an illustrious sire, discussed "Medicine as a Profession." He pointed out that the aim and object of life, from a worldly point of view, is to extract the largest possible amount of felicity from existence; that with many the accumulation of wealth loomed largely. Yet, while this was undoubtedly a material affair, still happiness and wealth were not synonymous. In order to get a living a man must adopt an occupation; for educated persons not only is a living requisite, but also some intellectual gratification, "the successful combination of which two elements is undoubtedly necessary for the attainment of happiness." He then went on, "The well-being of the community in great part depends upon the honor and moral rectitude of our profession, whose powers of doing good and evil are so unlimited." After which he inquired how the public had encouraged and appreciated those upon whose shoulders so much rested, and then went on to show how neither from a political, a social, nor a commercial aspect was medicine exalted, as compared to other callings in life. The doctor gets few honors from the state; his social position is not what it ought to be as one of the learned professions, and compared to the law and the church; and he continued, "There is no item in the expenditure of a household more grudgingly bestowed, more liable to be questioned, or more tardily settled than the doctor's bill." Now, if the editor of the *British Medical Journal* reads his journal, and remembers what he said some years ago, when the writer said something—the truth of which has been generally admitted—about the position of the profession, and compares it with these inaugural utterances, he ought to be a sadder and a wiser man now than he was then; though it is quite possible that such is not the case.

Having eased his mind as to the less fair side of medicine, the lecturer proceeded to paint its attractions. If the state paid it little attention, its freedom was all the greater; its charms were its own. If medicine had no great social status, it at least did not debar its members from high social position. Then he said something very true, and put it very well: "According to the respect with which he treats his own calling, and the courtesy and forbearance he exercises towards his colleagues, so will he raise his profession in the eyes of the world. Just as his relations with the public are dignified and honorable, so will he elevate himself above the adventurer and charlatan." And in this he struck a very weak spot in our professional armor. Then he went on to talk of the pleasure of knowledge, or, rather, that it brings with it. "The acquisition of knowledge of all kinds brings with it its own reward," he quoted. But it is not in student-life that the bulk of men feel this. It is when the hair begins to grow thin on the vertex or to turn gray that this aspect of knowledge dawns upon most of us. With the neophyte it is the examination-table on which he fixes his steady gaze. The lecturer felt this, and expressed himself

so in speaking of medical education: "This should aim at something higher than to prepare the pupil for the ordeal of the examiner or to obtain for him a legal qualification to practise. The real purpose is to initiate the student into the fundamental principles of medicine as a science and an art, to train his mind into habits of accurate observation, to cultivate a love of study, and to develop a taste for scientific pursuits." One wonders whether at this point Dr. Bennett was not indulging in a little sarcasm, as his father often did.

At St. George's Hospital, Dr. Champneys, the Assistant Obstetric Physician, gave the address, which dealt with "Midwifery as a Moral Training." He analyzed the motives which led men to enter the medical profession. Among them are, "first, the hope of being stamped or marked by the profession, and, secondly, the hope of leaving their stamp or mark upon it." He thought it spoke well for medicine that "our ranks are constantly swelling, and swelling with men whose education and social status appear to improve every year, in spite of the fact that its members are comparatively poor." Then he made a quotation: "There are three things which a poor man cannot afford to keep,—pride, a horse, and a conscience. All undoubtedly involve an outlay, or, in other words, a loss of money; but the first and third must be kept at all price, and the second acquired when necessary." He was glad that midwifery now had a recognized position, and that "it is now practically impossible to gain possession of any respectable diploma without the acquisition of a tolerable knowledge of midwifery and the diseases of women." He pointed out that in practice such knowledge, "almost more than any other," stands the practitioner in good stead, especially in the early part of his career; and, though neither have for years come specially under the writer's notice (except so far as disturbances connected with their sex are inseparable from women's troubles, whatever they ail—and that is almost always), he can fully indorse the lecturer's view. Women are grateful for knowledge which applies specially to themselves, and, what is more, their gratitude is rarely a purely negative matter with them. After which he pointed out how association with woman in her hour of need brought out the better and higher qualities of a man, and spoke truth therein. "To be a good practitioner," he remarked, "you must also have 'clean hands' (antiseptically as well as ethically) and a pure heart." He thought that watching nature manage her own affairs was a good broad rule: the more intimately a man knew her ways, the sooner he would be able to detect the first beginnings of mischief. The whole study of pregnancy and parturition he thought most excellent mental and moral training.

At the Middlesex Hospital, Dr. Finlay, Senior Assistant Physician and Lecturer on Forensic Medicine, delivered the address on the subject of "Preventive Medicine." He bewailed the fate of the unlucky Medical Bill, of which his predecessor, the year before, had spoken hopefully. "The daylight which had been let in by it upon some of the license-granting bodies had not been fruitless," he thought. He then dived into the subject proper of his discourse. We had made, he said, steady average progress, in the matter of the percentage of deaths from zymotic disease, since 1875, when the act pertaining to sanitation came into work. Sanitary medicine had made good its claims to public attention. Still, there was much left to be done which had in it promise of great results.

At Queen's College, Birmingham, the address was given by Dr. James Sawyer, Senior Physician to the Queen's Hospital, one of our best provincial physicians. He claimed that theirs was one of the best schools of medicine, not only in the provinces, but "in this or any other country." Some of his passages are well worthy of quotation. "Examination is the dominant 'note' of our current medical instruction. Two or three generations ago the leading principle of medical education was 'imitation.' Now the student sets before him examinations he has to pass; then the apprentice had a master to imitate. Now our teaching is professional, and to a class; then it was more personal, and to an individual. There is much that is good, doubtless, in our present system of medical education; but I am afraid we have scarcely preserved all that was good in the system we have set aside. I dare say we have been gaining in professional knowledge. Have we not been losing somewhat in professional wisdom? We have been growing in scientific precision. Have we not sometimes been loosening, and are we not in danger of losing, some of our best traditions?" There is a right good ring about that utterance! Then he pointed out that they came to college to gain knowledge. Hear what he has to say about knowledge: "Now, I am afraid many of you are apt to imagine—as most people do when they begin preparation for a particular career in practical business or professional life—that all you want now, and that all you need seek, as students, is knowledge. You have heard very often that knowledge is power, and you are prone to think that if you have knowledge all things else will be added unto you. But surely this is not so. Knowledge is not power, but only its material. Knowledge is only power when wisdom points its employment. Even now, and here, when and whither you have come to seek and find knowledge, you must seek and find wisdom too, if you would grow in skill and grace which the life you have chosen requires of you." Wisdom is refined

knowledge, which has a practical value, he continued. "When you have begun to apply knowledge in thought and action," he said, "to the best ends and true purposes of life, you have begun to be wise." He concluded by advising the study of the lives of those who have achieved success, as well as matter for the examination-table: "so you will learn how to prepare for professional life as well as for professional diplomas." And all right-thinking persons, who have the honor of medicine at heart, must agree with Dr. Sawyer, who has evidently "learned wisdom" as well as "acquired knowledge."

J. Milner Fothergill.

THE KENTUCKY STATE SANITARY COUNCIL.

THE interest in the proceedings of the Kentucky State Sanitary Council, both public and professional, grows with every semi-annual meeting. At Elizabethtown, that beautiful little city in the centre of Hardin County, the session of which I shall speak was opened on the evening of Wednesday, October 1.

As all such meetings go, there was, of course, the usual address of welcome by the orator of the place, which in this instance was delivered by the Hon. T. A. Robertson, Representative of the district in which the Council was held. The usual response to this was made by Mr. George Baber, of Louisville, President of the Council, and in his remarks he took occasion to speak nearly as follows:

"The Kentucky State Sanitary Council is a meeting of the citizens of an appointed place, together with those physicians of the State who, as public-spirited citizens, have an interest in the public health, to discuss ways and means to avoid the outbreak of contagious and infectious diseases, and as far as possible, when once established, to control their spread. It is a part of the object of such meetings also to awaken a keener interest generally upon all matters relating to the general health. As such, every intelligent citizen, regardless of avocation, of politics, of profession or standing, can and should take a deep interest in the subject and in the meeting. This movement, at first ridiculed by the secular press in the State, has come to receive not only the respect, but in some instances the support, of the press, and it has the interest of the best people enlisted everywhere."

At the close of Mr. Baber's remarks, the regular proceedings of the Council were begun. The first subject to engage the attention of the Council was "A Healthy Home," by Dr. Dudley S. Reynolds, of Louisville. He said in substance:

"We have so many things that tend to revert the attention to the old fireside and the old home that I felt especially honored upon being notified that I was expected to address this audience this evening upon such a popular subject.

"Man's first care in primeval times was to protect himself against extremes of temperature and the vicissitudes of climate, while at the same time he secured the materials for the maintenance of his life. Having secured these, necessity suggested an opening in his rude hut to let in the light and air to dispel the foul emanations of close confinement. Beginning with these simple and elementary ideas, the improvements in his surroundings and habitation were added one by one until the present time, so that now the consideration of the subject of a healthy home naturally divides itself into a discussion not alone of those conditions necessary to sustain life and to preserve health directly, but indirectly as well, by relating to the common dangers of neglect, of unfavorable location, or unsuitable climate, or limited means.

"The consideration of the factors of light and air alone is one of vast importance. They are factors of great importance, and factors too, unfortunately, much neglected in this day of crowded cities. To the air alone and what it contains we must look for the origin of all those diseases which we recognize as distinctly malarial. The consideration of the water-supply is one of equal import, as pertaining more directly to the nourishment of the body, and one of vast importance too, when we recognize it as the medium through which some of the most dangerous and terrible and devastating diseases find entrance to the human organism. We drink the cholera and the typhoid fever." The questions of food, clothing, sleep, and ventilation, together with cleanliness and drainage, called for separate attention, and, in conclusion, the subject of consumption, as due to improper attention to these subjects and as the result of neglect in securing wholesome surroundings, was discussed.

In the discussion which followed Dr. Reynolds's address, Dr. McCormack, of Bowling Green, said that an excellent authority had written that the style and architecture of the school-houses and churches of the people marked their advancement in civilization. He thought it might better be said that the home-life of a people was the true test of their advancement. This is a broad question. Lately the State Board of Health had been engaged in making a sanitary survey of Kentucky, inquiring on a large scale into the home-life and habits of the people. The result is not flattering to our vanity: carelessness in regard to the location, construction, and ventilation of our houses, and in regard to the disposal of house-refuse and kitchen-slops, had been reported from all sides, and the results of these neglects—typhoid and other fevers, diphtheria and other filth-diseases—

are widely prevalent. He pointed out the absence of all systematic attempts at ventilation of dwelling-houses, and also the relation of impure air to scrofula and consumption, as another evidence of home-neglect. This survey showed that only about one-third of the people of this State had been vaccinated. Thousands of dollars were paid from the county treasuries in Kentucky to treat and stamp out smallpox, which properly applied in vaccination would entirely prevent this disease. Cleanliness and carefulness in every home would make Kentucky what it should be,—the healthiest and greatest of the States.

Dr. Breyfogle thought the address of Dr. Reynolds was timely and most excellent, but that it did not go far enough into the subject of a healthy home; that the suggestions contained in the address applied more especially to people of the higher classes, those able to construct and own their own homes; that more attention should be paid to those poorer classes who are under the influence of landlords who care less for the physical than the financial condition of the tenants. We should teach them that these are not the only requirements for a healthy home; teach them that they swallow disease as often in stale vegetables, impure milk, and diseased meats, as from the emanations from garbage and cess-pools; teach them to look into their culinary department oftener; and then if the poor laborer, who goes to his work early, leaving his wife with the cares of a large family, should be unable to fully conform to the modern sanitary regulations in the removal of offal from his premises, they can at least remove some of the predisposing causes of an unhealthy home. Again, some reference should be made, in treating of a healthy home, to the moral influences, which contribute so often to debility, nervous prostration, and insomnia. In this we often find the secret germ which undermines the constitution and prepares the field for reception of the infinitesimal germs so learnedly discussed by my predecessors.

The reading of two papers, one upon the "Injurious Effects of Alcoholic Beverages," and another on "Alcoholic Liquors in their Relations to Health Laws and Regulations," created considerable discussion on Thursday morning.

Dr. Hugh D. Rodman, of New Haven, Kentucky, in the first drew attention to the effects of alcohol, first upon the separate organs of the individual physically, and then morally and mentally upon the man and those dependent upon the soundness and capability of his body for service for the improvement of their surroundings, and in this indirect manner their health. More particularly, however, it was to the effect upon the brain and nervous system of the man that the remarks of Dr. Rodman applied. He showed that a form of insanity, hopeless, irremediable, and perpetual, to which is usually, fortunately, a speedily fatal termination, is one of the common effects of the habitual use of alcohol in one or other of its forms of drink presented to the public; so common, in fact, that, out of one thousand insane patients coming under the observation of Dr. Morel, one of the authorities on the subject, two hundred were deranged through the action of alcoholic liquor. This proportion, in fact, is increasing.

In his report of 1877, Dr. Edgar Sheppard, who has charge of the male patients in the asylum of Colney Hatch, speaks as follows:

"A minute study of the admissions of this year clearly establishes the fact that twenty-eight per cent. of them ought to be ascribed to the excessive use of alcohol."

In the other paper, by Dr. P. C. Sutphin, of Canmer, the subject was treated from a different stand-point, and he raised the question of the necessity of legal enaction to enforce prohibition as a sanitary measure. He declared it useless to insist upon the removal of a closed sewer as a health-precaution, while the saloon and dram-shop, more powerful factors in the destruction of the powers and energies and health and welfare of the supporting elements of the race, were allowed to stand a monument of the cowardice and cupidity of all who claim to have at heart an interest in the health and well-being of Kentucky citizens. Drinkers of alcoholic stimulants, said the reader of the paper, are always the first to succumb to epidemic diseases such as yellow fever and cholera. In Glasgow, Scotland, in 1832, during the epidemic of cholera then prevailing, only nineteen per cent. of the temperate attacked perished, while ninety-one per cent. of the intemperate fell victims to the disease. In the same year at Montreal, of one thousand persons who died there of the disease, only two were teetotalers. Said one writer, "The disease has searched out the haunt of the drunkard, and has seldom left it without bearing off its victim. In New York city, of two hundred and four cases, only six were temperate men, and all of these recovered, while one hundred and twenty-two of the others died." The general drift of this paper might perhaps be well conveyed by the following paragraph:

"It may be said, however, that the Health Board has no power to remove the dram-shop. This may be true so far as the present is concerned, but that this power might be made a matter of the future, if so desired, perhaps admits of but little doubt."

The means by which this could be accomplished was entered upon by the writer of the paper, and afterwards discussed by the members present. The general conclusion of all the remarks and ideas expressed was that three factors might be brought to exercise an influence in this direction, a potent one of which would be by the introduction of the

subject into the common schools, in this way moulding and shaping the sentiments of the generation growing up; another, by enlisting the sympathies of the ministry in the subject, and still further by demanding of legislators those rights which belong to a majority of the people.

Dr. J. N. McCormack, of Bowling Green, read an interesting paper on the "Location and Construction of School-Houses." He was followed by Dr. C. Z. Aud, of Cecilian Junction, on "The Sanitary Science displayed in the Construction of Railroad Depots and Stations."

Dr. W. R. Jones read an interesting recital of a smallpox outbreak in Caldwell County, tracing, from the first case imported, the course of it until thirty-seven cases occurred, with a mortality of three, before it was suppressed by isolation, vaccination, and disinfection.

In the afternoon a paper was read by Dr. R. B. Pusey, of Elizabethtown, on the "Prevention of Cholera;" after which an illustrated lecture was given by Prof. J. A. Tanner, of Louisville, on "Food-Adulterations," which was somewhat surprising as showing the extent to which this practice is carried.

At the evening session a paper by Dr. John D. Bengless, of Brooklyn, New York, on "The Disposal of the Dead," was read by the Secretary.

The writer of this paper carefully traced the different methods adopted from the earliest times to the present, and gave the simplest reasons for their adoption, regarding the question in the beginning as one of convenience, and later as a kind of protection from desecration by wild beasts and hateful foes. Thus rock- and cave-burial was practised in rocky countries, where sepultures were formed by nature's hand. On broad alluvial plains the device most naturally suggesting itself under these conditions was to cover the body with earth directly where it fell. Experience soon teaching the people that a slight covering of earth afforded the dead little protection from the ravages either of driving storms or ravenous beasts or inhuman human enemies, a hole was dug beside the body, into which it was rolled and then covered. Hence the modern forms of the grave and the modern practice of earth-burial. Then he traced the reason for originating tree and scaffold disposition of the dead and of aquatic burial from both convenience and necessity under circumstances under which they are practised, and also explained some of the causes of cannibalism:

"The religious beliefs of various peoples have had much to do with their methods of disposal of the dead. The ancient Egyptians believed that, after three thousand years or more spent in varied states and experiences of transmigration, they would return to reinhabit the body. Wherefore they preserved it by a painstaking process of embalmment for rehabitation. They believed also that the viscera were the seat and source of all the debasing appetites and passions, and that in the re-embodied state there would be a complete freedom from every corrupting and defiling influence. Wherefore, before embalming, they eviscerated the bodies, that in the after-life they might be free from all debasing appetites.

"The Hindus, on the other hand, also believing with the Egyptians in the doctrine of metempsychosis, had such an utter abhorrence of the thought of returning to the body once inhabited on earth, that they sought most sedulously its utter destruction in order to avoid the possibility of such return. To this end they burned it to ashes and scattered the ashes upon the winds and waves, that it might not be possible for the particles to find each other and to come again together.

"The belief of a portion of the Shinto sect among the Japanese in the literal resurrection of the body and a new birth leads them to bury it in a large womb-shaped urn, the body being posed in the urn precisely as the unborn infant rests in the womb, the knees being drawn up under the arms and the hands folded over the breast. In order further to facilitate and guarantee beyond all peradventure this new birth, the original umbilical cord which at birth attached the child, and which through all the years of life has been preserved for this purpose, is placed in the urn with the body. So it has been held by some that all entombment was originally intended to be a species of enwombment, in order that, thus placed in 'mother earth,' the dead might rest in hope of a new birth and of a future life.

"Who, and when, and where was the bold man who first proposed the burning of his brother's body and executed his proposition, and what the motives prompting that proposition, we are not informed. Two things concerning him would seem self-evident: he must have been a brave man to make the proposition, and he must have had reasons for it which induced others to assent to it and assist in its execution. We may surmise that the practice originated on the battle-field, where conquered soldiery resorted to the burning of the bodies of their fallen comrades to save them from indignity and mutilation by the conquerors. Thus originating as a tribute of affection to the heroic dead of the battle-field, cremation might readily and speedily attain the distinction which we know it afterwards held among the Greeks and Romans, and even among the Hebrews, of a rite of honor bestowed at first only upon distinguished persons, and ever denied to criminals, outcasts, and to unteethed infants and women dying in uncleanliness. That in its early history cremation had all the sanitary, æsthetic, and economical advantages which

array themselves in its support in modern times and when conducted according to the most approved modern methods, cannot be claimed. On the contrary, cremation by the open pyre, as usually conducted, by reason of the spice-wood and oils, not to speak of sacrificial offerings burned upon and in the pyre, was costly to a degree. Instead of having about it anything to recommend it to the sensibilities of the refined, it was shockingly barbarous in the seething and torturing action of the flames upon the members of the subject, and, despite the lavish expenditure of spices and perfumes, was inexpressibly offensive in its exhalations. And yet, despite its offensiveness and its expensiveness, cremation became and was for centuries the preferred method of disposal of the dead throughout by far the greater part of the then civilized world. That it should have been superseded by earth-burial is sufficiently accounted for not only by reason of its offensiveness and its great cost, but also by the fact that it rapidly denuded of wood the whole face of lands where it was practised, making fuel so expensive that few could afford a respectable funeral-pile, which became, through the Grecian and Roman empires, almost as costly a luxury as is with us the modern funeral.

"The chief agency, however, in bringing about the change was the spread of Christianity, and this for two reasons: (*a*) the founder of this religion having, upon his death, been entombed, according to the prevailing custom of his people at this time, his followers thought to be like him in following him to the grave, which would not have been so objectionable if they had always been careful to get in 'a new tomb hewn out of a rock,' and then to stay there less than three days, as did he. (*b*) The other consideration was the hostility evinced by Christians to all pagan rites and institutions, cremation among the rest, and their anxiety to do and to be anything and everything that would tend to distinguish them from the pagans among whom they dwelt. Wherefore, as fast as men embraced Christianity they abandoned the pagan practice of cremation. With few exceptions, the people of those times chose neither their religion nor their rulers, insomuch that by royal or imperial decree a hitherto 'pagan' nation became 'Christian' in a day, and the practice of cremation, which once prevailed over almost the entire territory of Europe and Western Asia, from India and Scythia on the east, where it is believed to have had its origin, to the Hyperborean Sea upon the west, and from the Grecian Isles to Scandinavia, was abandoned, except in India, and the practice of inhumation became almost universal. The natives of India, however, have, as a rule, ever retained the practice of cremation, and the influence of their example has travelled eastward into Corea and Japan.

*

"If one desires to know the relative merits of the two practices, he cannot do better than to compare the sanitary conditions in this respect of the Chinese and the Japanese, or, in India, the condition of Buddhists and Brahmins, who practised the cremation of the dead, with that of the Mussulman population, who practised earth-burial. China, in the region of its cities, for miles around is a vast, hideous, and pestilential burial-ground, while Japan, in the vicinity of its centres of population, is a land of gardens, wherein grow fruits and flowers and all that in the vegetable kingdom can minister to the comfort and happiness of man. The contrast would be yet more marked if the entire population of Japan practised cremation, instead of only a part of it, and especially were that practice in accordance with approved modern methods, instead of being in great part by the open pyre.

"Much as religious prejudices have had to do with determining the methods of disposal of the dead, there is yet no really essential relation existing between cremation and religion; and as enlightened views obtain, people everywhere are learning more and more that the disposal of their dead is a purely sanitary, economical, and æsthetic question, and that religion has to do only with the life that is and with the immortal part of man in the life to come.

"More and more also are we learning that, whether in the grave or in the crematory fire, and whether in an hour or a hundred years, the body must be dissolved into its constituent elements; that this process of resolution is simply one of oxidation, or burning, as more familiarly known to us. In the grave it is 'cremacausis,' as the distinguished Liebig designated it: a slow burning amid festering putrescence. In the rosy glow of the crematorium it is rapid burning in cleanliness and light,—but burning in either case.

"While, however, the conditions and the process cannot affect, as to the body itself, the ultimate result, as to the effects upon surviving friends and neighbors of the deceased, and upon the sanitary conditions of the region round about, the differences of effects are just the difference between health and disease,—the difference between life and death.

"In the language of Sir Henry Thompson, 'No dead body can be put into the ground without poisoning the earth, the air, and the water about and above it.' Within a few hours, or days at most, after death, the decomposing body is pervaded with bacteria, or microbian organisms, which, together with all the offensive gases developed in the process of putrefaction, are struggling with each other in foul *mêlée*, each seeking to escape from its loathsome imprisonment.

"The body, chemists tell us, is more than three-fourths water, much of which in the

process of decomposition percolates through the earth and finds its way into the neighboring water-courses, carrying with it not only the bacteria engendered in the putrefactive process, but the deadly nitrates and nitrites which give to grave-fed waters their peculiarly enticing brilliancy, while the carbonic acid gas, the carburetted and sulphuretted hydrogen, and other noxious gases, together with numberless microbian organisms, find their way out to the surface to exert their baleful influence upon the relatives and friends of the departed who in tender ministry visit the loved one's grave, and those ministering friends carry with them from the cemetery headaches, sore throats, malaria, typhoidal symptoms, diphtheria, scarlet fever, and numerous other ills, contracted they wonder how, or when, or where.

"Every burial-ground is a magazine wherein we store the seeds of disease to which flesh is heir, to come forth thence we think not how or when, to prey upon us when we are least prepared to resist their attacks. In these thousands of acres, among the fairest and most beautiful of all the land, which in the vicinity of our great centres of population we sequestrate from the living and give over to the dead, we are thus storing the germs of every form of zymotic contagion, there to await the most favorable conditions for their most perfect development and for their most efficient and most deadly work.

"In all that has been said it is assumed that earth-burial is as complete and satisfactory as possible. But how seldom is this the case! How frequently, especially in times of epidemics, is it superficial and incomplete, thus affording the disease-germs the most favorable opportunity for development, and so converting our cemeteries into very hot-beds of contagion!

"Such is the heritage which we are laying up for posterity. And when our children and our children's children come for stress of space to build their homes in these old burial-grounds or to convert them into parks to be breathing-places and play-grounds for their children, they will wonder how and why these beautiful elevated situations can be so malarial, and why their systems seem to have no tone and stamina for the resistance of disease. The public buildings, including hospitals, and the public squares of many of our cities occupy the sites of the burial-grounds and potters'-fields of generations gone.

"Hannibal encamped in the old Campo Santo outside the city of Syracuse, and took the marble tombs to build a barricade from which to besiege the city, and after a brief siege Hannibal and his army were carried off by the pestilence which resulted from disturbing the old burial-ground. The unseen arrows of disease, sped from the bows of the dead, not the spears of the living Syracusans, slew and scattered the Carthaginian hosts. So the dead ever avenge themselves upon those who recklessly invade their domain.

"Let us, then, cease to surrender our fairest hill-tops and hill-sides to the dead, for they will convert them into citadels from which to hurl their poisoned arrows into the city of the living, until all shall be together in common burial blent. These fair slopes and summits are needed for the occupancy of the living, and cannot in justice be surrendered to the dead.

"Instead of thrusting our loved ones who have departed this life into the gloomy grave, there to fester in loathsome putrefaction and thence to come forth in all ghastly forms of dreaded disease, let us reverently, decorously, and expeditiously translate them by means of the all-purifying fire into the elements of all new and beauteous life. So shall our fair land become indeed, as it should be, 'the land of the living,' and not 'the valley of the shadow of death.'"

Following the reading of this paper, Prof. L. Eddy, of Danville, read one on the subject of "Sanitation a Religious Duty."

In this paper the sanitary regulations of the early nations of which we have an account in the Bible were referred to. The lecturer said that it is plain that thorough sanitation was a religious duty of the Hebrews.

"We believe that the presence of an atmosphere of filth lessens human powers, certainly shortens life, and may at any time suddenly terminate it. We believe the seeds of some diseases float in the air, that the seeds of others are in drinking-water, and that they enter the system by the help of these agents. We believe that these germs, many of them, can be destroyed. We believe that in a perfect state of physical health the seeds of many diseases cannot gain a foothold in the human system, but that filth is a most powerful agent to so weaken the body that disease-germs can readily affect it. We believe that filth, using the term in its broad sanitary sense, is to-day mowing down the human ranks as Minié-balls mow down the ranks of an army in battle. If this is true, a responsibility rests upon us for the existence of filth around us, and where there is responsibility there is corresponding duty. 'Cleanliness is next to godliness,' and our lives should be lives of warfare against sin in the shape of dirt, so that, conquered though we be at the last, yet, when we lie down in a good old age, there will be no cause for us to utter the lament of the woman immortalized in the 'Housekeeper's Tragedy:'

"'With Grease and with Grime from corner to centre
Forever at war, and forever alert,
No rest for a day, lest the enemy enter,
I spend my whole life in a struggle with dirt.

'Last night in my dreams I was stationed forever
On a bare little isle in the midst of the sea;
My one chance of life was a ceaseless endeavor
To sweep off the waves ere they swept over me.

'Alas! 'twas no dream! Again I behold it!
I yield; I am hopeless my fate to avert!'
She rolled down her sleeves, her apron she folded,
Then lay down and died, and was buried in dirt!"

Following Prof. Eddy, Dr. William Cheatham, of Louisville, read a paper on "Near-sightedness in School-Children, its Dangers and Prevention," after which his remarks were illustrated by illuminated plates in the magic lantern.

After tendering a vote of thanks to the citizens of Elizabethtown by the visiting delegates for the courtesies and hospitalities shown them, the Council adjourned, to meet at Bowling Green in April, 1885.

ALLEN KELCH, M.D.

MEETING OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

THE Twelfth Annual Session of the American Public Health Association, held at St. Louis, Missouri, October 14 to 17, was one of the most successful ever held. The attendance was as full as usual, but the number of the papers presented was larger than ever before in the history of the organization. I would like to say as much for the quality of the papers, but candor compels the statement that many of them failed to come up to the standard which the Association ought to demand. As usual, a few of the papers were exceptionally valuable, either from their scientific character or their practical importance.

The first paper read gave a review of the reforms demanded by sanitarians in the "Construction of Habitations for the Poor." The author, Dr. C. W. Chancellor, of Baltimore, suggested that an unsanitary house should be declared a public nuisance and dealt with accordingly. Only in this manner could the law reach the difficulty.

Major S. A. Robinson, of Washington, followed with an excellent practical account of how to construct healthy habitations for the poorer classes. He considered in detail the site, water- and drainage-fixtures, light, and ventilation. This was one of the best papers presented during the meeting. The speaker showed by his manner of treating the subject that he had a thorough practical acquaintance with all its details. The same may be said of a paper of great interest to the practical sanitarian, by Dr. W. K. Newton, of Paterson, New Jersey, describing how the sanitary survey of a house should be conducted.

Drs. George H. Rohé, of Baltimore, Walter Wyman, United States Marine Hospital Service, and Adolph Alt, of St. Louis, read papers on the "Hygiene of Occupations." The essay of Dr. Rohé was statistical, and showed, numerically, the influence of certain occupations upon health and the duration of life. Mortality-tables published in 1874 by the Massachusetts Bureau of Registration were analyzed, and their results compared with those derived from European sources. The trades and occupations dangerous to health were briefly indicated.

The paper of Dr. Wyman concerned itself exclusively with the dangers and hardships of the oystermen engaged in the oyster-fisheries on Chesapeake Bay. The rapacity and brutality of the employers, and the extremely hazardous nature of the occupation, were graphically described.

Dr. Alt referred to the numerous cases of ocular diseases attributable to mechanical injuries in certain occupations, especially stone-cutters. He proposes that employers be made pecuniarily liable for injuries sustained by workmen if these result from neglect of proper precautions which can be enforced by the former.

The President, Dr. A. L. Gihon, Medical Director United States Navy, delivered a very brilliant address at the close of the first day's session. It was an eloquent appeal for more earnest personal interest in practical hygiene.

Among the papers read were several on adulterated and disease-producing foods. Dr. J. Cheston Morris, of Philadelphia, discussed "The Adulteration of Milk and the Milk-Supply of Large Cities." He recited the evils of impure and adulterated milk, and recommended that sealed glass jars should be used for the transportation of milk. In this way the adulteration of the milk in transit between the producer and consumer could be guarded against. A simple method of testing the purity of the milk should be placed in the hands of the consumer, and in this way fraud on the part of the producer could be detected. Dr. B. F. Davenport, of Boston, showed how the inspection of milk had resulted in great improvement in the character of the supply furnished in the latter city.

Hon. Erastus Brooks, of New York, read an essay on "Food and Food-Adulteration," in which the subject was well treated, and many statistics given showing the extreme extent to which many of the common articles of food and medicines are sophisticated.

Prof. V. C. Vaughan, of the University of Michigan, gave an account of an outbreak of cheese-poisoning recently observed in Michigan. Over three hundred cases of poisoning from eating cheese had occurred in that State within the past six months. None of the cases were fatal. The symptoms were those of intense gastro-intestinal irritation. The cheese which produced the morbid effects was excessively acid. A practical method of detecting the acidity was by the use of litmus-paper, which any grocer or householder could apply. Excessive acidity of the cheese should arouse suspicion concerning its quality.

Dr. Charles Smart, United States Army, read a paper on the "Water-Analysis of the Future," in which the present defective methods were criticised. Dr. H. B. Baker, of

Michigan, drew attention to the relation of the depth of the soil-water to the spread of typhoid fever in that State. This paper was illustrated by charts which clearly showed the coincidence of a low ground-water level and increased prevalence of typhoid fever, and *vice versa.*

Dr. Joseph Holt, of New Orleans, described the new system of quarantine which it was proposed to introduce at the outlet of the Mississippi River. The system consists of absolute disinfection of passengers, baggage, cargo, and ship, and only incidental detention. Dr. Holt's plan found much favor with most of the members. There can be no question of its superiority, if properly carried out, over any other system now in use.

Several interesting papers on "School Hygiene" and on "Cremation" were read, and both subjects referred to committees.

Dr. J. F. Hibbard, of Indiana, introduced a resolution to investigate the subject of germicides, disinfectants, and antiseptics in their relations to preventive medicine, to formulate the result of their inquiries, and to submit the same at the meeting of the State Boards of Health, in Washington, on the second Tuesday in December. The committee was constituted for practical work, and consists of Dr. Geo. M. Sternberg, United States Army, chairman; Dr. J. H. Raymond, of Brooklyn; Prof. V. C. Vaughan, of Ann Arbor; Dr. W. H. Watkins, of New Orleans; Dr. Chas. Smart, United States Army; Prof. A. R. Leeds, of New Jersey, and Dr. George H. Rohé, of Baltimore.

Dr. Jas. E. Reeves, of Wheeling, read a report of an elaborate sanitary survey of the Ohio River for the first one hundred miles of its course, and showed the relations of the river to the sewage-disposal and water-supply of the cities and towns along its banks. Dr. E. S. Elder, of Indiana, read an extremely valuable report embodying the results of a sanitary survey of the school-houses in that State. It is very desirable that this sort of work should be continued. Measures of reform can only be intelligently introduced after the actual conditions needing reform are thoroughly understood.

The most important outcome of the meeting was the offer on the part of one of the members of the Association, Mr. Henry S. Lomb, of Rochester, to place two thousand dollars in the hands of a committee, to be distributed in prizes of the value of five hundred dollars each. Mr. Lomb has also headed a subscription-list with fifty dollars to defray the necessary expenses of the committee on disinfectants and antiseptics, above referred to. Mr. Lomb, who is known at his home as a practical philanthropist, is a member of the microscope-manufacturing firm of Bausch & Lomb.

The prizes are to be open to universal competition, and the following subjects are suggested by Mr. Lomb and the committee having the matter in charge;

1. Healthy Homes and Foods for the Working-Classes.

2. Sanitary Conditions and Necessities of School-Houses and School Life.

3. Disinfectants and Individual Prophylaxis against Infectious Diseases.

4. Appliances and Means for Saving Life, and for Protection against Injurious Influences of Occupations upon Health.

The committee to act as judges will consist of one member appointed by the National Board of Health, three appointed by the Executive Committee of the American Public Health Association, and one by the President of the Conference of State Health Boards. All essays must be handed to the committee before the 1st of April, 1885. The conditions of the competition will be announced through the medical journals. It is intended, I believe, that the essays shall be short and practical, in order that the mass of the people to be benefited can be reached and properly influenced. Elaborate theoretical dissertations will stand very little chance of winning a prize.

A notable feature of the meeting was the illustrated lecture by Dr. Geo. M. Sternberg, the distinguished mycologist, on "Disease-Germs." For nearly two hours the lecturer held the attention of a large audience while showing various examples of innocent and pathogenic micro-organisms by means of micro-photographs and the magic lantern.

The officers elected for the ensuing year are:

President.—Dr. Jas. E. Reeves, of West Virginia.

First Vice-President.—Hon. Erastus Brooks, of New York.

Second Vice-President.—Dr. Henry B. Baker, of Michigan.

Treasurer.— Dr. J. Berrien Lindsley, of Tennessee.

Executive Committee.—Drs. H. P. Walcott, of Massachusetts; C. Smart, United States Army; G. B. Thornton, of Tennessee; D. W. Hand, of Minnesota, and H. B. Horlbeck, of South Carolina.

Too much praise cannot be awarded to the local committee and the citizens of St. Louis for their active efforts to make the meeting pleasant and successful. All the clubs and places of interest were open to the members of the Association, the city was illuminated in their honor, and carriages were at their disposal for rides through the city and parks. I should fail in my duty did I not mention the names of those largely instrumental in securing these advantages to the Association. They are Dr. J. G. Spiegelhalter, chairman, and Dr. Geo. Homan, secretary of the local committee. It was a matter of considerable comment, however, that the medical profession in St. Louis contributed but a small portion

of the attendance at the sessions. The thought is forced upon one that St. Louis doctors take very little interest in sanitary progress. Another noticeable thing was that representatives from Chicago and Cincinnati were conspicuous by their absence. Can this be accounted for by local jealousies?

The next meeting will be held in Washington, in December, 1885.

Among the distinctively medical movements now in progress in St. Louis is the organization of a Post-Graduate School and Polyclinic. A fine building is in course of erection, and will be ready for occupation in the spring. The members of the new faculty are Drs. W. A. Hardaway, dermatology; H. N. Spencer, otology; W. C. Glasgow, laryngology; C. E. Michel, ophthalmology; J. K. Bauduy, neurology; Geo. J. Engelmann, gynæcology; P. G. Robinson, general medicine; H. Tuholske, surgery, and A. J. Steele, orthopædic surgery. Most of these are at present connected with the Missouri Medical College, of which the Polyclinic seems to be an outgrowth.

The medical schools here have pretty fair classes, and the teachers in the Missouri and St. Louis Medical Colleges seem fairly to represent the best portion of the profession.

CORSAIR.

ST. LOUIS, October 17, 1884.

PROCEEDINGS OF SOCIETIES.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held October 2, 1884, FORDYCE BARKER, M.D., LL.D., President, in the chair.

Dr. F. H. BOSWORTH read a paper on

THE THREE TONSILS: SOME PRACTICAL SUGGESTIONS AS TO THEIR STRUCTURE, FUNCTION, AND DISEASES.

The author said he had for some time entertained certain views with regard to the three tonsils different from those usually expressed in medical literature. Speaking of the three tonsils he meant the two glandular masses found between the pillars of the fauces and that found in the vault of the pharynx, the latter first recognized and described by William Hunter. The former were called the faucial tonsils, and the latter the pharyngeal tonsil.

The faucial tonsils are not, as generally described, covered by a fibrous sheath, nor are they necessarily almond-shaped, but of whatever shape the morbid process may have given them. The tonsil is not an organ of the body in the sense that the liver or spleen constitutes an organ, and therefore it has no special function to perform in the animal economy. Virtually there are no tonsils: the organs so called do not exist in the healthy throat, but are the result of a morbid process. All mucous membranes are richly endowed with glands, and perhaps no portion of the mucous tract calls for a greater amount of mucus in the performance of its function than do the upper air-passages, and here we find the glands aggregated in masses. In a condition of health this aggregation of glands does not project prominently from the mucous membrane, nor is their existence easily demonstrated by gross inspection. But the mucous membrane of the upper air-tract is liable to repeated attacks of inflammation, especially in the young, and the tendency of a chronic inflammatory process is to develop hypertrophy in these glands. Dr. Bosworth considered that the only function of the masses of glands in question is to supply mucus or lubricating fluid.

The three tonsils are liable to the same diseased conditions. These might be considered under the heads acute follicular tonsillitis, subacute tonsillitis, croupous and diphtheritic inflammation of the tonsils, and hypertrophy. He did not believe that phlegmonous inflammation ever occurrs in the tonsils, and thought that quinsy was rather a disease of the cellular tissue of the fauces than of the tonsils. It involved the areolar tissue, especially of the soft palate, in rare instances of the pharyngeal walls, but not the glands. He believed it to be usually due to the rheumatic habit. Within the past three years one hundred and thirty-three cases had come under his observation, eighty-eight cases being males and forty-five females. The oldest patient was 69 years, and the youngest 9 months of age. Of the entire number of cases the phlegmon occurred in the soft palate in one hundred and fifteen cases; in the pillars in eleven cases; beneath the tonsil in two cases, but in the tonsil proper in no case. A large number of cases of quinsy were aborted by the administration of the salicylates, and when not aborted the medicine seemed to hasten suppuration. He gave a tablespoonful, every two hours, of a solution containing three drachms of the salicylate of soda in six ounces of water. He had also found the bicarbonate of soda useful, as recommended by Dr. Barker, but not equally efficacious with the salicylate. If an abscess formed, it should be treated as an abscess of any other portion of the body,—by incision.

Dr. Bosworth thought that in acute follicular tonsillitis there is a greater amount of constitutional disturbance and fever than could be accounted for by the local affection, and he had been led to regard it as one of the essential fevers, liable to recurrence.

Hypertrophied tonsils give rise to a train of symptoms mainly due to mechanical obstruction of the passages. The enlarged tonsil shows a tendency to subside at the age of puberty. It develops purely from a local

morbid process, and is not the manifestation of a dyscrasia. Hypertrophy of the pharyngeal tonsil had been described by many writers as adenoid tumors or vegetations of the vault of the pharynx. If the hypertrophied tissue offer a mechanical obstruction, it should be removed. Local medication, he believed, had no effect whatever in reducing genuine hypertrophy of the glands. It had been suggested that only a portion of the tonsil be removed; but there was no more reason for this than there was for removing only a portion of a tumor developed elsewhere on the body. The danger from hemorrhage has been exaggerated. In children there is only a slight amount of bleeding; and if in the adult considerable hemorrhage should arise, it could best be checked by the actual cautery. It would be found to come only from the nutrient artery, and on arterial hemorrhage styptics had no effect. Injury to the carotid artery is an unpardonable blunder, and is not to be considered as a danger of the operation.

DISCUSSION.

The PRESIDENT called upon several gentlemen, not specialists in diseases of the throat, to discuss the paper, because of their experience with certain points contained in it. He first said, with regard to his use of the bicarbonate of soda in quinsy, mentioned by the author, that he had been in the habit of seeing a few cases of quinsy each year, and, until some years ago, they almost invariably ended in suppuration. But, since he had begun the local application of bicarbonate of soda, in not a few of the cases the disease was aborted. A marked instance of the kind occurred in a patient seen with Dr. Bosworth, a gentleman of eminence in literature, who was suffering greatly from threatening abscess. The next morning after the use of the remedy he was found at the breakfast-table.

Dr. DOUGLAS would agree with the author on most points, but there were a few with which he must take exception. He would agree with him, for example, that quinsy was a manifestation of rheumatism, or, especially, of gout, and the treatment which he had employed for this affection was largely that used by the President, namely, bicarbonate of soda. At the same time he gave the ordinary remedies against gout. He had found the gargle and spray of bicarbonate of soda also useful in cases of enlarged tonsil; but one of the most beneficial remedies for this class of cases was a powder composed of one part of menthol to a hundred parts of sugar of milk. He would not always resort to the knife for the removal of the enlarged tonsil. It could be slowly but surely reduced in size by the persistent use of a powder composed of salt, camphor, ammonia, and sugar of milk.

Dr. F. H. HAMILTON was inclined to agree with Dr. Bosworth that the enlarged tonsil should be removed by the knife; yet he had often observed that the enlarged tonsil of childhood disappeared before the twentieth year. He supposed that the author, when he said there was no danger connected with removal of the tonsil, meant to except the acute or engorged state, and cases of the hemorrhagic diathesis. The question had been raised whether all or only a part of the tonsil should be removed: he should say all that the knife would include.

Dr. JACOBI believed that the only efficient treatment for the enlarged tonsil was its removal. Applications would not reduce its size, and where they had apparently done so the reduction was due to some other cause. The enlarged tonsil might remain stationary and appear smaller after the lapse of years because of the growth of the fauces. As to the danger of hemorrhage, there usually was but little loss of blood, but it might be profuse from cutting into the soft palate,—an accident which could not always be avoided. The most efficient means for stopping hemorrhage when it occurred was digital compression, applied perhaps for an hour or more. He could not agree with the author's view that follicular tonsillitis was an essential fever. He looked upon it as a local disease. What Dr. Bosworth took to be an essential fever was probably diphtheria, for cases of diphtheria were often overlooked or mistaken for some other affection. It was a great mistake to suppose that every patient sick with diphtheria must necessarily die. There were many mild cases which went unrecognized, and which were all the more dangerous for that reason, as they were the more likely to spread the disease. Dr. Jacobi laid particular stress upon this point because of its importance to the public health.

Dr. WEBER had not yet seen a case which went to substantiate the view that a phlegmonous inflammation around the tonsils was due to the gouty habit. He had found it most frequently in patients of poor general health.

The PRESIDENT remarked that guaiacum had once been strongly recommended in the treatment of quinsy on account of the supposed gouty origin of the affection, but he had not obtained the results with it which he had been led to anticipate from reading certain articles in the medical journals.

Dr. POST thought the best treatment for the enlarged tonsil was extirpation.

Dr. HAMILTON had found the external application of ice or snow the best means for checking hemorrhage after removal of the tonsil.

Dr. FRUITNIGHT had aborted some cases of quinsy by the administration of the tincture of aconite.

Dr. JARVIS again called attention to a distinction which he had made between the soft and hard or indurated enlarged tonsil, the

latter being found in the syphilitic. If the scirrhous tonsil were cut, it would surely give rise to hemorrhage, and might result fatally. He employed the knife in the removal of the soft enlarged tonsil, and the cautery or snare in the removal of the scirrhous tonsil. He did not think any more of the tonsil should be removed than was necessary, for it doubtless served some physiological purpose, as the lubricating of the fauces and protecting the carotid artery.

Dr. BRANDEIS said he believed in the Darwinian theory of the survival of the fittest: the tonsils had survived some thousand years, fulfilled some physiological purpose, and he doubted not that they performed their function well, whatever it might be. But they, like other structures, were liable to disease, and a diseased tonsil might be worse than no tonsil at all, and therefore he believed it should in proper cases be extirpated. He then pointed out the advantages of the tonsillotome over the knife in certain cases. Contrary to the experience of Dr. Bosworth, he had found hemorrhage in young subjects rather than in the adult, although not extreme. To prevent hemorrhage, he allowed the patient to sip a solution of tannic acid, and, if necessary, he applied pressure. Dr. Bosworth's description of quinsy corresponded with that in Ziemssen's Cyclopædia, there called peri-tonsillitis, but Dr. Brandeis could not accept the view that it was always an inflammation of the peri-tonsillar sheath. He recommended aconite and the ammoniated tincture of guaiacum in its treatment until an abscess should have formed.

Dr. CORNING had arrested a severe hemorrhage after tonsillotomy in one case by the use of his carotid compressor.

Dr. BOSWORTH, in closing the discussion, said, with regard to the possibility of reducing the size of the tonsils by astringents, that he believed it could not be done. Their size, however, might be reduced in the young, in whom they were in a state of chronic inflammation, by undergoing contracture. This would account for the diminished size of the tonsils on reaching adult life. As to hemorrhage in the young, it was only an oozing; considerable hemorrhage occurred only in the adult. That tonsillotomy was not dangerous was apparent from the fact that in all medical literature not a single fatal case was recorded. The cases in which the carotid artery had been wounded were excepted. This accident could never occur in the hands of a surgeon. In arresting hemorrhage with the actual cautery, the iron should be applied from above downward, that it might not be cooled by the flow of blood before coming in contact with the bleeding vessel He regarded peritonsillitis as a very good name for quinsy, but he did not believe there was a peri-tonsillar capsule proper. As to the tonsils performing their function, he did not believe they existed in the normal state, but that they were the result of disease.

The Academy then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held October 8, 1884, GEORGE F. SHRADY, M.D., President, in the chair.

CANCER OF THE STOMACH.

Dr. SATTERTHWAITE presented the stomach, pancreas, heart, and kidneys of a man 53 years of age, whom he was called to see in consultation on the 7th of September of the present year. The patient had had a hemiplegic attack, the right upper and lower extremities being slightly involved, but recovering within twenty-four hours. He had lost flesh rapidly during the last month, and gradually during the past two years. His physician had not been able to make out any special disease, the heart, lungs, and urine appearing to be normal; he had suffered some pain in the epigastric region, but no tumor could be felt. During the last month the patient had not been able to retain solid food longer than from twenty-four to forty-eight hours, when it would be vomited up with a good deal of effort. The cachectic appearance developed. About two weeks before death another hemiplegic attack occurred, and, besides losing power over the right extremities, there was also difficulty with speech and swallowing, but this, after a time, almost entirely disappeared. During the last four or five days of life the patient refused to eat, on the ground that his food would not stay down, and he preferred starvation to the pain and vomiting. Death took place from starvation.

At the post-mortem examination a circular patch, of the size of a silver half-dollar, was found at one side of the pyloric end of the stomach, not apparent to the eye, but readily felt with the finger. The pyloric opening admitted only a lead-pencil. This patch undoubtedly acted as a valve at times, and obstructed the exit of food from the stomach. There were some nodules in the pancreas, and parenchymatous nephritis. The specimens from the stomach and pancreas had not yet been examined microscopically, Dr. Satterthwaite preferring to exhibit them in the fresh state, but doubtless the disease was carcinoma.

The PRESIDENT thought that malignant disease should have made greater progress within two years.

Dr. SATTERTHWAITE had seen a case in which the nodule at the pylorus had been recognized two years before death, and symptoms of cancer had existed for a longer time.

Dr. J. C. PETERS thought this specimen might possibly turn out a duplicate of the first

one presented to the Society in 1844. In that case the patient had had somewhat similar symptoms, and at the post-mortem examination it was expected that the thickening which was present in the stomach would be found to be cancerous, but it proved to be simply thickening of the areolar tissue. It was regarded as a rare condition.

Dr. CARPENTER referred to a case in which a cancerous nodule over an inch in diameter, situated three inches from the pylorus, was found at the post-mortem examination, no gastric symptoms having been present during life.

NASO-PHARYNGEAL FIBRO-SARCOMA.

Dr. LINCOLN removed the specimen, July 22, from a boy 16 years of age, who had never been very strong, and who had always suffered from nasal catarrh. He first noticed obstruction to nasal respiration and tumor in 1881. From this date he had suffered from frequent severe nasal hemorrhage, usually coming on after active exercise, but sometimes during sleep. A physician had attempted to remove the tumor, which could then be seen through the nostril and mouth, by the ordinary polypus forceps, but failed. Dr. Lincoln saw the patient first through the courtesy of Dr. Satterthwaite on July 12, at which time there was a noticeable fulness on the right side of the nose; the right nostril was filled to the margin by the growth, which pressed the septum to the left; the soft palate was deflected to the perpendicular, and below it, filling the naso-pharyngeal space, the tumor could be seen, apparently having its principal attachments to the vault of the pharynx and roof of the nostril. It was exceedingly vascular, and evidently growing rapidly, and therefore an immediate operation was advised without preliminary treatment by electrolysis. On July 22 the galvano-cautery wire was applied to the base of the tumor while the patient was under the influence of an anæsthetic, and Dr. Lincoln succeeded in cutting through the pedicle and drawing the tumor out entire through the mouth, no hemorrhage taking place during the operation. The tumor measured in its greatest length four inches, and two and a half inches in thickness. The surface of attachment, which measured two inches by one and three-fourths, was then cauterized. The weight of the growth was two ounces and three-fourths. A week after the operation the cut surface presented a healthy appearance. The patient had not yet consented to a reapplication of the cautery for the purpose of preventing redevelopment of the growth.

The PRESIDENT thought there could be no comparison between this mode of operating and the old mode of preliminary tracheotomy, tamponing the pharynx, and removing the upper jaw. It seemed, however, that there were some cases of naso-pharyngeal tumors in which the wire could not be applied to the base of the tumor on account of its extensive attachments. He mentioned two cases in which he operated by removal of the upper jaw, the tumor having extensive attachments to the base of the skull, etc. One of the patients died of shock, apparently due to an extension of the growth into the skull, and in the second case the result was similar, although death took place later. He now had a patient who was begging for a similar operation, but he hoped first to have a consultation with Dr. Lincoln as to the advisability of trying the galvano-cautery. The great difficulty in this class of cases was that usually they did not come to the surgeon until it was impossible to apply the wire, and the general health was too greatly reduced from repeated hemorrhages, etc., to make success from a surgical operation at all probable.

Dr. HOWE thought that even in the bad cases referred to, with such extensive attachments, the tumor might be removed piecemeal by the wire.

The PRESIDENT had had one such case, in which a gentleman skilled in this manner of operating had removed a portion of the tumor with the wire, and, while the patient's condition was much improved thereby, the pain consequent on ulceration at the points where the wire had been applied deterred him from submitting to further treatment.

Dr. SATTERTHWAITE thought the operation which Dr. Lincoln had performed, at which he was present, had required a great deal of manual dexterity. A distinguished throat-specialist had said that the tumor could not be removed except by first removing the upper jaw, but Dr. Lincoln performed the operation with the galvano-cautery wire with a single application of the loop. The patient had had no hemorrhages since the operation, and had gained greatly in flesh and strength. He had been impressed very favorably with the operation, and would be glad to hear Dr. Lincoln's further experience with it.

Dr. LINCOLN said he had had six cases, two of which were still undergoing treatment. Of the other four cases he believed there was no possibility of recurrence. He had had no fatal result. With regard to the difficulties overcome during the operation, he referred to a case operated upon in 1876. The patient had been operated upon by Dr. Willard Parker, and also by Dr. Lutkins, who referred him to Dr. Lincoln. At the time when he saw him, the boy, five and a half feet high, weighed only sixty-eight pounds. His condition was such that death seemed inevitable; several surgeons had said that no interference by treatment was justifiable. The tumor had so developed as to cause protrusion of the right eye, projected through the nostril to the margin of the upper lip, and in the mouth to such an extent that the tongue had to be depressed at night by the spatula to enable the patient

to sleep. There had been frequent hemorrhages. Dr. Lincoln began preliminary treatment by electrolysis, making about twenty-five applications. The growth of the tumor was thus checked, hemorrhage ceased, and the patient recuperated so that the final operation could be undertaken with perfect safety. The wire was applied, the tumor was removed entire without any hemorrhage; some applications of the cautery were made subsequently, and there had not been any signs of return of the growth since. The other cases were similar, but not quite so pronounced.

FIBRO-CYST OF THE UTERUS.

Dr. PRUDDEN presented a specimen which had been sent him by Dr. C. C. Stockard, of Columbus, Mississippi, and the history of which had been published in the *Medical Record*, August 16, 1884. It was interesting principally on account of its large size. Together with the fluid contents, which had been drawn off six days before death, it weighed one hundred and thirty-five pounds. Eight gallons and seven pints of fluid had been withdrawn by tapping. The microscopical examination showed the specimen to be a fibroma of the uterus. It had developed in a negress who had borne children.

FATAL INTESTINAL OBSTRUCTION.

Dr. C. W. KNIGHT presented a part of the intestine and uterus, which had been removed from the body of a negress, 35 years of age, unmarried, who had been the subject of constipation for a good many years, with frequent attacks of colic, but she never consulted a physician. Frequently her bowels did not move once in two weeks. After her last attack had existed two weeks, she began to take purgative medicines, and the third week sent for a physician, who found no constitutional disturbance. She was up and about her room until the last day of life, when she began to vomit copiously, had enormous distention of the abdomen, and died suddenly. At the autopsy the small intestine was found to be distended and congested, and about five inches from the cæcum there was a constriction between two fibrous bands, which had produced a furrowed appearance in the gut, but had not caused ulceration. The obstruction was immediately relieved on cutting the constricting bands. There were also fibroids in the uterus.

THE NEW ENGLAND JOURNAL OF DENTISTRY has become united with and merged into the *Dental Association Journal*, which will hereafter be published as the *Archives of Dentistry*. Preparations are making on an extensive scale for editorial collaboration from all parts of the country, and no effort will be spared to make the *Archives* a national and representative dental journal.

REVIEWS AND BOOK NOTICES.

DIPHTHERIA, CROUP, ETC.; OR, THE MEMBRANOUS DISEASES, THEIR NATURE, HISTORY, CAUSES, AND TREATMENT; WITH A REVIEW OF THE PREVAILING THEORIES AND PRACTICE OF THE MEDICAL PROFESSION; ALSO, A DELINEATION OF THE NEW CHLORAL-HYDRATE METHOD OF TREATING THE SAME, ITS SUPERIOR SUCCESS, AND ITS TITLE TO BE CONSIDERED A SPECIFIC. By C. B. GALENTIN, M.D. Small 8vo, pp. 174. New York, J. H. Vail & Co., 1884.

We give the title of this little book in full, in order to be understood when we say that the same literary fault mars the book that mars the title.

The author has produced a work which is too large for a tract and too small for a treatise and combines many of the faults of both with few of the virtues of either. It has a vice of comprehensiveness. Having something to say, he has forgotten that brevity is the soul of wit, and so obscured it with tediousness, the limbs and outward flourishes of wit, that the thing to be said seems scarcely said at all.

This is much to be regretted, because the gist of the matter, namely, the treatment of diphtheria by the chloral hydrate both constitutionally and locally, is of great importance, and would have attracted wide attention if the author had presented his views and the results of his experience in a compact, practical article in one of the journals.

We believe that this mode of treatment—which, by the way, is not so exclusively his own as the author appears to think—is an excellent one, and we agree with him in his views as to the questionable value of iron and potassium chlorate. We regret that the good he seeks to do is likely to be restricted by the form he has selected for the publication of his opinions. J. C. W.

SHAKESPEARE AS A PHYSICIAN. By J. PORTMAN CHESNEY, M.D. J. H. Chambers & Co., Chicago, St. Louis, Atlanta, 1884. Cloth, 8vo, pp. 226.

"O, the recorders!—let me see one."—*Hamlet.*

The aim of the author of this work is to record—grouped under the headings of Obstetrics, Psychology, Neurology, Pharmacologia, Etiology, Dermatology, Organology, Chirurgery, and Miscellaneous—every word which in any way relates to medicine found in the complete works of Shakespeare (which text is not stated); and, if he had done no more than this, the work would have had both interest and value. The digressions, irrelevant quotations, and almanac anecdotes which pad the book are out of place, and should have been omitted. Considerable labor has been spent upon the compilation,

but it is marred by this evident effort at book-making. Sixteen wood-cuts more or less adorn the pages of the work, one-half of which have absolutely nothing whatever to do with Shakespeare, but illustrate topics entirely foreign to the text. Their irrelevancy and value may be judged by some of their titles: An Illustration of the Benefits of Protracted Lactation; Enquiry on Lunacy (Medical Experts to the Right); The Doctor looks for the Skeleton behind Him; The Effects of Gathering May-Apple Root; The Woodman and his Arrangement for Cheap Boarding; The famous "Dr. Sunrise" condescends to visit the Good People of St. Joseph. If this book was intended to advance the literary reputation of the author, it might be appropriately introduced by a quotation from "Love's Labor's Lost." F. W.

Drugs and Medicines of North America. A Quarterly devoted to the Historical and Scientific Discussion of the Botany, Pharmacy, Chemistry, and Therapeutics of the Medicinal Plants of North America, their Constituents, Products, and Sophistications. J. N. Lloyd & C. G. Lloyd, Cincinnati, 1884.

This handsomely-printed quarterly, devoted to a special department of materia medica, contains many valuable illustrations, and is a welcome addition to the literature of our indigenous flora. The high price of such works usually debars many from possessing them; but this publication, at one dollar per year, is free from this objection, and will find many appreciative and interested readers. The contents of the three numbers which have so far appeared show careful preparation, and are highly creditable.

The Medical Record Visiting-List for 1885, published by William Wood & Co., is out, and can be obtained, with or without dates, for thirty or sixty patients per week. It is handsomely bound in morocco, and is a durable and useful visiting-list.

GLEANINGS FROM EXCHANGES.

Operative Opening of Pulmonary Cavities.—Dr. E. Bull (Christiania), in a paper on this subject, read at the International Medical Congress, Copenhagen, laid down the following propositions: 1. Abscesses of the lung which can be diagnosticated with certainty, and are so situated that they can be opened through the chest-wall, should be treated in the same way as pleural empyema. 2. The condition is the same with regard to limited gangrene of the lung. If several gangrenous foci exist, each one must be treated separately. 3. Echinococci, and, 4, foreign bodies in the lung are to be treated in a similar manner. 5. In bronchiectasis the formation of a pulmonary fistula is indicated only when the accumulation of stagnant matter in large cavities essentially contributes to the deterioration of the patient's condition. 6. In rare cases of tuberculosis, where a large cavity is the predominating condition, the cavity may be laid open with the view of improving the condition of the patient. 7. The operative puncture of a pulmonary fistula is justifiable as a palliative measure. 8. In cases where diagnosis cannot be arrived at, exploratory puncture is certainly of much value; positive as well as negative results may be derived from it. 9. Adhesion of the layers of the pleura ought not to be insisted on as an absolutely necessary preliminary to the opening of pulmonary cavities. 10. Amyloid degeneration is not an absolute contra-indication to a palliative operation. 11. The use of the thermo-cautery is to be recommended both for the opening of cavities and for the destruction of diseased portions of lung-tissue.—*British Medical Journal.*

Comedones.—At the last meeting of the American Dermatological Society, Dr. A. Van Harlingen recommended for the treatment of comedones a paste composed of glycerin, three parts; vinegar, two parts; and kaolin, four parts. This, which had been first suggested by Unna, he regarded as having decided value.

The English Commission sent to investigate the cause of the cholera in India are now busily prosecuting the work at Bombay. It is announced that Dr. Klein has swallowed some of the comma-bacilli without evil results.

MISCELLANY.

Severe Punishment of a Druggist.—The case of a druggist in the upper part of the city, who has recently been found guilty of involuntary manslaughter by a jury because of a mistake which caused the death of a child, calls for a word of comment. Mr. Heintzelmann, the unfortunate druggist referred to, has been engaged in his business in this city for over twenty years, and has in that time earned an enviable reputation for devotion to his work, and for skill, attention, and carefulness, among physicians as well as the community at large. The mistake, it appears, was made in his store, though, he claims, not by him personally. He adopts the check-system for prescriptions, which indicates his great caution: this was not proof, however, against an ignorant woman picking up the wrong medicine, which happened to be a liniment instead of a baby-syrup. Although the bottle was decorated with skull and cross-bones and plainly marked "poison" and "for external use," this woman, who declares that she cannot read, administered some to her baby, who died of lead- and laudanum-poisoning, for which the coroner held the

apothecary responsible. Although the medicine was very different from what the description given by the doctor had led her to expect that it would be, and despite its bad taste and smell, three teaspoonful doses were deliberately given by the mother of the child, at intervals of two hours, and not until then was the physician sent for, who detected the mistake; but the child was already moribund. It would really seem as if the druggist had taken every reasonable precaution, first by requiring a check, and secondly by placing the word "poison" and the symbol on the bottle, and that his responsibility should not be increased in order to accommodate exceptional ignorance. Contributory negligence was clearly present upon the part of the attendants of the child, who should have examined the medicine as soon as received, and returned it for explanation. It certainly does not seem right that exemplary punishment should be visited upon the druggist-defendant in this case; and we hope that his application for a new trial will be granted, in order that the case may be more fully considered, and that the responsibility may be more justly apportioned.

A CURIOUS case in regard to the removal of the dead came up recently in the Surrogate's Court, at Brooklyn, New York, under the following circumstances:

Gardiner H. Wolcott died at Astoria in November, 1881, and was buried in Greenwood Cemetery, at Brooklyn. He was supposed to be intestate, and his property, amounting to about forty thousand dollars, was divided up among the next of kin. Not long since a will was found in which was the following provision: "It is my special command that my remains lie beside those of my darling Nina's in Greendale Cemetery. Any expense in carrying out this wish will be paid from my estate."

Greendale Cemetery is situated at Meadville, Pa., and the Nina mentioned was an actress named Nina Varian. He was supposed to be unmarried, but there was some evidence that she was in reality his wife. The question then came up, Shall the testator's wish as to a burial-place be carried out? The estate was divided up, and the executor had no means of defraying the expenses.

Under these circumstances he applied to the Surrogate's Court for an order requiring the persons who had received the estate to pay the expense of removal according to their respective shares. The relatives opposed the application, and the Surrogate denied it.

It was clear that if the will had been found at the time of death, or before the distribution, the removal might have been carried out by the executor; but the Surrogate now says, "The direction of a court should not be sought to authorize the executors to incur an additional expense when the immediate parties interested in the estate will have to be called upon to bear their proportionate expenses while they at the same time are strongly protesting against the removal of the remains."

A REMARKABLE FAMILY QUARREL.—A novel point in the law of the home came up recently in Ohio, where a father asked a court to grant him an injunction against his two sons living at home, and upon his showing the case was a strong one. The sons were 33 and 26 years of age respectively, unmarried, strong, and able to earn their own living. The father said they had never paid anything for their board, and that when requested to leave the house they had refused. They had also been so violent about the house, and had used such profane language, as to make their mother sick, and both of them afraid of their lives. The furniture had also been broken by them during some of their freaks. The judge granted a temporary injunction, and the case is to come up for a further hearing.

THE first issue of the *Medical Chronicle*, of Manchester, England, edited by Jas. Niven, M.A., M.B., and W. J. Sinclair, and published under the direction of an able committee, has been received. It is a monthly of large octavo size, 120 pages, printed on white paper, with clear type, and presents a very attractive appearance. The contents of the initial number include five original communications, besides a chronicle of nearly a hundred pages of progress in the several departments of medicine. The journal is ably edited, and will be received with favor by the profession.

THE DONATION of half a million dollars to the College of Physicians and Surgeons of New York by Wm. H. Vanderbilt is one that commands admiration for the feelings which prompted the gift and the wisdom shown in the choice of an object for the donor's munificence. It is understood that a plot of ground two hundred by three hundred and fifty feet, between Fifty-ninth and Sixtieth Streets, opposite Roosevelt Hospital, has been chosen. There is ample room for future development of the college, and for the erection of laboratories and other buildings as needed.

THE *Therapeutic Gazette*, published by Mr. Geo. S. Davis, of Detroit, will hereafter be edited by Prof. H. C. Wood and R. Meade Smith. It is announced that the editorial office will be in this city. The *Gazette* has already achieved marked success in its field, and under its present management its usefulness to both pharmacology and therapeutics will be undoubtedly advanced, and the journal kept at a high standard.

THE EPIDEMIC OF CHOLERA IN ITALY has brought out, in an unexpected way, a curious relation existing between the medical profession and the public. Sanitary officers engaged in their duties in some of the small villages have been mobbed, while physicians

found patients who refused their aid and looked upon their ministrations with marked and open mistrust.

In the daily press we observe that Judge Tourgee is credited with the statement that the pathway to success is so plain in the professions of law, medicine, and theology that it almost requires the possession of genius in order to fail in any of them. He maintains an eloquent silence with regard to the profession of journalism: does he mean to imply that the same rule holds good, or is it reversed?

Encyclopædia of Medical Wit, Humor, and Curiosities of Medicine.—Julius Wise, M.D., proposes to publish a large volume with the above title, and respectfully solicits the kindly aid of the profession in collecting material suitable for the work. His address is 806 Olive Street, St. Louis, Missouri.

The reception given by the Pathological Society to Dr. Delafield, of New York, on the 22d of October, was a success. Among the invited guests were Profs. Mallett and Osler.

In Kent sixty-nine persons were poisoned by, and one died from, eating shrimps which had been taken from near the mouth of a sewer.—*British Medical Journal*, October 11.

NOTES AND QUERIES.

OBITUARY.

Professor Louis Alexander Dugas, M.D., of Augusta, Georgia, died October 19, in the seventy-ninth year of his age. Born in Washington, Georgia, in 1806, he studied medicine with Dr. Dent, of Augusta, and was graduated in 1827 from the University of Maryland. After several years' study in Europe, he returned to his native State, and was one of the founders of the Medical College of Georgia, in which he held the chair of Surgery during the remainder of his life. The University of Georgia conferred the degree of Doctor of Laws upon him in 1869. He was one of the Vice-Presidents of the International Medical Congress held in Philadelphia in 1876, and was repeatedly elected President of his State Medical Society. He was editor of the *Southern Medical and Surgical Journal* for a number of years.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM OCTOBER 12, 1884, *TO OCTOBER* 25, 1884.

Norris, Basil, Lieutenant-Colonel and Surgeon.—Relieved from duty as attending-surgeon, Washington, D. C., and ordered for duty as Medical Director Division of the Pacific and Department of California, relieving Surgeon E. I. Bailey. Col. Bailey, on being relieved, will assume the duties of attending-surgeon at San Francisco, California.

Spenser, William C., Major and Surgeon.—From Department of Dakota to Department of the East.

Goddard, Charles E., Major and Surgeon.—To be relieved from duty at Jefferson Barracks, Missouri, and to report for duty in Department of Dakota.

McClellan, Ely, Major and Surgeon.—From Department of the East to duty at Cavalry Depot, Jefferson Barracks, Missouri.
S. O. 242, A. G. O., October 15, 1884.

McKee, James C., Major and Surgeon.—Granted leave of absence for one month, with permission to apply at division headquarters for one month's extension. Paragraph 1, S. O. 149, Department of Colorado, October 3, 1884.

Alden, Charles H., Major and Surgeon.—Relieved from duty at Fort Yates, Dakota Territory, and ordered for duty at Fort Snelling, Minnesota. S. O. 125, Department of Dakota, October 20, 1884.

Wolverton, W. D., Major and Surgeon.—Granted one month's leave of absence, to take effect when his services can be spared by his post commander. Paragraph 4, S. O. 211, Department of the East, October 16, 1884.

Vickery, R. S., Major and Surgeon.—During temporary absence of Major J. C. McKee, Surgeon, U.S.A., Medical Director of the Department, in addition to his other duties, will assume charge of the office of the Medical Director. G. O. 34, Headquarters Department of Colorado, October 8, 1884.

Winne, C. K., Captain and Assistant-Surgeon.—In addition to his duties as post surgeon at Benicia Barracks, will also attend the sick at Benicia Arsenal, California. S. O. 122, Headquarters Department of California, October 13, 1884.

Havard, Valery, Captain and Assistant-Surgeon.—Assigned to temporary duty at Fort Schuyler, New York Harbor, New York. Paragraph 2, S. O. 211, Department of the East, October 16, 1884.

Porter, J. Y., Captain and Assistant-Surgeon.—Granted leave of absence for one month, on surgeon's certificate of disability, with permission to leave the limits of the Department. Paragraph 3, S. O. 138, Headquarters Department of Texas, October 9, 1884. Confirms telegraphic order of same date.

Strong, Norton, First-Lieutenant and Assistant-Surgeon.—Assigned to duty at Fort Union, New Mexico. S. O. 198, Department of Missouri, October 4, 1884.

Phillips, John L., First-Lieutenant and Assistant-Surgeon.—Transferred from Department of the East to Department of Dakota. S. O. 245, A. G. O., October 18, 1884.

LIST OF CHANGES OF STATIONS OF NAVAL MEDICAL OFFICERS FROM OCTOBER 12, 1884, *TO OCTOBER* 25, 1884.

Surgeon George R. Brush, to temporary duty at the Naval Laboratory, October 11, 1884.

Medical Inspector Charles H. Burbank, detached from the "Brooklyn," and placed on waiting orders, October 15, 1884.

Surgeon John H. Clark, detached from the "Lackawanna," and detailed as fleet-surgeon of the Pacific station, October 17, 1884.

Surgeon George H. Cooke, to the "Lackawanna," October 17, 1884.

P. A. Surgeon John M. Edgar, to the Receiving-Ship "Franklin," October 11, 1884.

Medical Inspector A. Hudson, detached from the "Lancaster," and placed on waiting orders, October 14, 1884.

Surgeon Joseph Hugg, placed on waiting orders, October 13, 1884.

P. A. Surgeon P. A. Lovering, detached from the "Lackawanna," and placed on waiting orders, October 17, 1884.

P. A. Surgeon F. H. Marsteller, detached from the "Monongahela" and ordered to the "Lackawanna," October 17, 1884.

Assistant Surgeon William Martin, detached from the "Passaic," and placed on waiting orders, October 14, 1884.

P. A. Surgeon H. M. Martin, detached from the "Brooklyn," and placed on waiting orders.

Delavan Bloodgood, promoted to the grade of Medical Director, August 22, 1884.

Aaron S. Oberly, promoted to the grade of Medical Inspector, March 28, 1884.

Henry M. Wells, promoted to the grade of Medical Inspector, August 22, 1884.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON MODERN METHODS OF TREATING PULMONARY PHTHISIS, AND WHAT WE SHOULD EXPECT FROM THEM.

Being an Abstract of a Lecture delivered at the Bellevue Hospital Medical College, October 28, 1884,

BY BEVERLEY ROBINSON, M.D.

GENTLEMEN,—You will remember that at my last lecture I told you that in many forms of stomachal disease, but particularly in atonic dyspepsia accompanied by marked fermentative changes in the ingesta, I had found, when other methods failed, the use of lavage by means of the soft-rubber tube a most valuable operation; indeed, I said, when the *hot-water* treatment was insufficient, it was the only plan to follow. I spoke to you of several cases in my experience which strengthened my statement, and I referred you to others with which I was familiar. I am glad to bring before you to-day a young man who is at present in my service at St. Luke's Hospital, and whose experience is amply sufficient to show the marked beneficial effects obtainable from daily washings. This young man states, as you have just heard, that he was formerly a very robust lad. After an acute affection, from which he suffered some months ago, he was attacked with severe acute dyspepsia. In fact, this symptom became so aggravated that he could digest no kind of food. Even peptonized milk would lie as a weight in his stomach, and frequently was rejected some time after being swallowed. Under these conditions daily washing-out of the stomach with warm water and borax (℥ss–Oij) was begun. Very soon he improved notably. His appetite was better, his strength increased, and in a week or two he was able to digest with ease certain light articles of diet. At this date he is no longer under active treatment with the œsophageal tube, and can digest roast or broiled meats, soups, milk, and bread, but cannot as yet digest vegetables. The number of successive lavages required to produce this result was seventy-seven.

This patient has acquired great facility in the introduction of the stomach-tube, and will now show you how readily he accomplishes this little feat. Please notice, as he pushes the soft-rubber tube backward and downward slowly, or again quite rapidly, he makes continual efforts at deglutition, and also breathes at a normal frequency. Now that the tube is in the stomach, you see that he is not apparently uncomfortable; it does not excite vomiting, or even nausea, and he can reply to any question, if addressed to him, without special effort. In order to show you how such a patient may be fed, I shall pour down the funnel and connecting rubber tubing a certain amount of this milk-and-egg, which was brought here at my request by one of the other patients, who is suffering from localized pain and dysphagia, due to advanced laryngeal phthisis. You see, our man takes his milk-and-egg very quietly, and I could go on perfectly well and pour into his stomach the entire contents of this pitcher, and probably do so with satisfaction to him. As it is, the demonstration is entirely satisfactory, and I now proceed to the subject of my lecture of to-day, which shall be mainly in regard to what I shall designate as "Modern Methods of Treating Pulmonary Phthisis, and what we should expect from them."

First, however, allow me to direct your attention for a few moments to the poor fellow who sits here. This man came to see me the other day, complaining chiefly of dysphagia and pain in his throat. The difficulty of deglutition does not exist to any very marked degree for liquids, but for solids it is extreme. Indeed, for more than six months he has swallowed little or no solid food, so that at present his appearance is that of excessive emaciation and weakness. His dysphagia is due, first, to the fact that the alimentary bolus in passing the larynx appears to go the wrong way, and the effort to swallow is followed immediately by a severe paroxysm of cough, and by rejection of food by mouth and nose. Occasionally, when food has evidently entered the larynx, he has nearly suffocated before he could free his respiratory tract from obstruction. But this is not all. The mere passage of solid food causes intense local pain, which he very much dreads, and from which he recovers slowly, and after a severe shock

to his system. Upon examination of this patient's throat, I find that he has advanced ulcerative phthisical laryngitis. The epiglottis is half eaten away, and, but for the fact that he denies syphilitic disease, shows no signs of its existence, and has evident pulmonary phthisis at its second stage in the region of the left apex, I should almost be persuaded that he had tertiary syphilis of the larynx. Further, I would add that my patient says the pain in his larynx at night is so intense that it prevents him from sleeping. Can we help him, and in what way? As a matter of fact, I find, gentlemen, he is greatly relieved from local pain by means of insufflations of a powder into his larynx of one part of tannin and two parts of iodoform; but I doubt very much whether these insufflations will do more than alleviate his sufferings for a time, unless we assist him to eat more nutritious food and in larger quantities. Here, if ever, there is a case for super-alimentation, and with the aid of the soft-rubber œsophageal tube (gavage). He should begin with a pint of milk, three raw eggs, and Reed & Carnrick's beef peptonoids, in ounce doses, poured into his stomach twice or three times a day. So soon as his stomach will bear more at any one feeding, it should be given more. When I recommend beef peptonoids I do not recommend what is best, for the powdered meat of Favrot,* according to Millard, is, doubtless, superior. This preparation, therefore, if procurable, should first be asked for, and if it cannot be obtained, then the beef peptonoids may be substituted as the next best and most suitable form of meat and gluten that we can use. Of course, the employment of super-alimentation does not interdict the use of the powder locally, nor does it absolve us from the duty, so soon as we can, of employing all other means, medicinal and hygienic, to cure our patient if possible. But bear in mind one very important fact, gentlemen, and over and beyond all theories in regard to the parasitic cause of tubercular disease of the lungs or larynx, that in most of these cases we have abundant proof of malnutrition and wasting. Do whatever else you choose and can, but first give your patients sufficient food to more than neutralize all waste or inanition. Some of these patients eat fairly well, have a tolerable appetite, but do not take *enough*. Give them more abundantly. Sometimes they can be persuaded to take large quantities of food for a while,—more than their appetite demands,—but soon food taken in this way disgusts even the best disposed and most yielding patient, and he finally declines to submit further. Then is the time to advocate strongly the use of the œsophageal tube for purposes of alimentation. Explain to him that lack of appetite, or repugnance to food when swallowed voluntarily, is no proof that large quantities, if introduced mechanically, cannot be thoroughly digested and assimilated. Numerous facts prove the contrary. You have only to read the remarkable histories first recorded by Debove and Dujardin-Beaumetz, and since verified, corroborated, and amplified by Dr. Millard, of this city, to be assured that super-alimentation is possible in patients who have at first the most pronounced aversion for food.

Further, what results can we obtain if we persist in thus feeding phthisical patients? The most remarkable and satisfactory. Many cases, of undoubted authenticity, have been published already, in which advanced cases of pulmonary phthisis have been permanently cured, thanks to super-alimentation, in this manner, continued without interruption during a series of months. Physical evidences even of softening at the apices have disappeared entirely, and all rational symptoms, such as hectic, night-sweats, elevated temperature, cough, dyspnœa, profuse expectoration, repeated hæmoptyses, have been completely suppressed for a period of time sufficient to guarantee complete recovery.

In addition to super-alimentation, I would urge the utility of continuous inhalation of dry vapors of certain volatile substances, such as creasote, carbolic acid, turpentine, iodine, eucalyptus, and benzoin. Since Curschmann, Roberts, Yeo, Pepper, and others have spoken favorably of these inhalations, I have made quite extensive use of them in both hospital and private practice. Judging by my own experience, I cannot believe that these inhalations are able by themselves to effect very considerable reparative changes in larynges or lungs already far advanced in

* This preparation has been imported by E. Fougera & Co., New York City.

phthisical lesions. I am quite confident, however, that they often lessen very much the frequency and intensity of cough, deodorize and diminish somewhat the quantity of sputa, and give considerable relief at times to painful sensations, both in the throat and chest, of such patients. I have shown you at a previous lecture the forms of inhalers I employ. The first kind is made of two perforated metal plates held together by a spring-catch, and between the plates a layer of oakum or absorbent cotton is placed, upon which a sufficient quantity of the volatile liquid is poured. They are held in place over the mouth by means of two elastic loops, which are passed around the ears. This form of inhaler is sold in this city by Mr. Ford, and was first introduced to the profession, I believe, by Dr. F. P. Kinnicutt. The other form, which I consider preferable, although much cheaper, was imported by me for use in the out-patient department of the New York Hospital. It is composed of a single piece of perforated light metal somewhat pyramidal in shape, and having attached at the apex of the pyramid a small piece of sponge, which, after moistening with water, should contain the volatile liquid. These inhalers can be worn during several hours each day without occasioning much annoyance, and with very decided relief to many distressing symptoms. They are unquestionably far superior to all other kinds of inhalers hitherto brought into use. They never give fresh attacks of cold, as I have frequently found with the warm-vapor inhalations was the case. They are very portable, readily put on and taken off, and their cost is moderate. The undiluted dry vapors, when inspired, probably reach as far down the respiratory tract as any atomized fluid from the numerous spray producers in the market, and appear to me in every way preferable to them.

This other patient whom you see is affected with pulmonary phthisis, which has reached the stage of softening at the left apex. He has no laryngeal complication, and yet he has most distressing and obstinate cough. To combat this symptom all ordinary means have been exhausted, and without giving even temporary relief. One week ago I injected ten minims of dilute Lugol's solution into the second left intercostal space, in a vertical line with the left nipple, and to the depth of one and one-half inches. The effect of this injection was to lessen his cough very much, and to make, as he states, his breathing somewhat easier. To-day I shall repeat this injection over the same region, and you will note the immediate result. It causes, as you perceive, but little pain, and, although the man coughs a few times immediately after the injection, and expectorates some thick, yellow phlegm, the sputa are not even tinged with blood. This is not always true, for in a few instances, after making similar injections, there has been slight hæmoptysis. I have thus far made about seventeen or eighteen of these intra-pulmonary injections, and with satisfactory results, so far as the cough and dyspnœa are concerned. The patients, in two or three instances, have affirmed that the quantity of sputa had also lessened. As yet, I have not followed up any one case long enough to know what definite results I shall obtain with respect to the pulmonary lesion itself.

In this country we owe this method to the personal initiative of the distinguished professor of practice at the University of Pennsylvania, Dr. William Pepper. In all, Dr. Pepper has performed more than two hundred intra-pulmonary injections, and has never had, so far as I know, one disastrous result. In fact, only on one occasion did he have a hemorrhage following the injection which appeared grave at the time. Even this hemorrhage seemed to be due to the suction caused by a considerable vacuum in the pump of Dieulafoy's aspirator. Dr. Pepper has given the first intercostal spaces as the proper places on the anterior chest-wall to make these injections. From my own investigations in the dead-house, I incline to the belief that the upper portion of the inner axillary region will be ultimately found to be the most direct way of reaching the cavities situated at the apices. To be frank, however, I should state that on two occasions, when I made injections at this spot, I had some bloody sputa follow the little operation.

What may we hope from intra-pulmonary injections? In my belief, they will disinfect the contents of lung-cavities; they will modify and diminish the secretions from the walls of these cavities; they will tend to effect cicatrization and contraction of these spaces, usually filled

with a material which is a constant source of peril to the patient. I have not been convinced of the advantage to the patient, when bearer of a phthisical cavity, of a free opening through the chest-wall and complete drainage of it. But this is a very different matter from the operation you have just seen, which may be repeated again and again without risk or shock to the patient, and which promises well to the sufferer, if he has the faith to hold out until the good results are noted.

I have endeavored in this lecture, gentlemen, to give you a slight *aperçu* of what I consider real advances in the treatment of pulmonary phthisis. We all know what treatment by the old methods means for the vast number of unfortunate beings who crowd our city dispensaries. With the three methods advocated by me before you this day,—viz., super-alimentation, continuous dry inhalation, intra-pulmonary injections,—many patients will yet be saved who, with cod-liver oil and the hypophosphites alone, or added to the other resources usually employed, would most certainly die. Nothing prevents us from using all previous means to help our phthisical sufferers, but I would also make a very urgent plea for the plan you have seen me practise before you.

ORIGINAL COMMUNICATIONS.

THE TRADE-ASPECT OF MEDICINE.

BY ALBERT L. GIHON, A.M., M.D.,

Medical Director U. S. Navy; First Vice-President American Academy of Medicine.

Read before the Academy of Medicine, and Recommended for Publication.

"THAT was a fearful experience you had in that typhoon in the Japan Sea," once remarked a very dear and very eminent friend, whose memory I revere, "but I almost wish you had been drowned;" and when I inquired why he would I had had such a doleful ending, with a merry twinkle of his eye, he added, "Because you would not have written that paper proclaiming the deplorable degree of ignorance in the medical profession." "Is it not all true?" I queried; and he answered, "Ay! that's the mischief of it; it is all too true. The fact is, the shiftless city pilled-garlick, or the country leech whom you see sitting in front of his rude shanty like the monthly nurse and village blacksmith, only plies his trade." And these words he spoke seriously, sadly, despondingly.

Let us look facts squarely in the face. Are there in our ranks, ninety thousand strong, mechanic surgeons, men midwives, and tradesmen doctors? and, if so, have they a right to the honors and consideration that pertain to the other members of the profession of medicine? If not,—and assuredly they have not,—how can the fact be made patent that they are only camp-followers, and not of the rank and file of a noble army of men enlisted, organized, and drilled to serve a great and glorious cause?

One does not have to go into country towns or sparsely-settled wilds to find the medical tradesman's sign. A very short time ago a leading medical journal, itself a foremost advocate of all that is elevating and ennobling in medicine, published a communication from an M.D., who was not even ashamed to append his name to the degree, bewailing that certain medical officers of the army had treated sick people in his neighborhood, and therefore, inferentially, deprived him of a possible fee. That the element of special locality and personality may be eliminated, I right-off plead guilty, as a medical officer of the navy, to the same offence, and further admit I know of many others, in both services, who have done and propose again to do likewise, whenever they can relieve suffering, restore health, or, in any other way within their power, benefit a human creature or an afflicted brute. The wail of this complaint might therefore be allowed to pass unheeded, but that it serves to illustrate the tradesman's spirit which has been engrafted upon a noble stock, which it threatens to overrule and cause to bear only its own unsavory fruit. He writes as he feels, and he feels as the corner grocer whose gall is stirred because some other vender, who has offered better or more tempting wares, has cut down his own sales. The advertising insignia and artifices, the gold-headed badge of office, the borrowed clerical necktie, the pompous air, the insinuated advice, the covert innuendo, have, perchance, failed to lure patrons to the shop where calomel and quinine are retailed instead of soap and molasses. He denounces "the unfair

competition" (and competition is the soul of trade), "because," he alleges, "the army surgeon is backed by an assured salary. The office he occupies and the horse and buggy he uses are in part paid for by the very physicians against whom he comes in competition. To the military medical mind this may seem fair and honorable; to the civilian, however, it certainly does not;"* and from the tradesman's point of view it is mean, I admit, to borrow the sounding-gong of your rival's milk-wagon and make him help pay besides for hawking your wares.

It does not mend the matter if this army-interloper makes no charge for his services; that aggravates the offence, for the medical tradesman profoundly detests charity and charities. The public dispensaries, hospitals, and lying-in asylums, the college clinics and their out-door poor-service, are regarded by him with the same disfavor that the old-time operative entertained for the thing that was moved by steam and did the work of a hundred clumsy, horny hands. Not that the new net catches more fish than he could even hope with his hook and line, but that it scoops in some gudgeon which might perchance have bitten his bait. Little recks he that the half-starved widow pays with her blood for his questionable advice and more than useless dose. The mantle of charity that would shield her and her puny children might envelop some parsimonious invalid who could afford to pay.

But charity is not the weightiest obstacle to success in medical trade. That may thin the crop, but as nothing in comparison with the blight called sanitary reform, which even medical men are fomenting. The tradesman's soul is sore as he sees the thistles on which he has fed uprooted from the fields where he has browsed. You will not find him at hygienic congresses, nor sitting on State boards of health, cheek by jowl with homœopaths and eclectics and other hated heretics and schismatics; nor leading sanitary associations, sanitary councils, or sanitary conferences; for, to his mind, it is downright folly to choke up the source whence lucre flows, though, to him, never but in a shallow stream. Sections in State medicine do not delude him with the borrowed plumage of their names, for what "medicine" is there in them or in that synonymous incongruity, *preventive medicine*, that should interest a man who wants to know the last gynæcological wonder, the latest way to cure bleeding piles or dumb ague, or the most recent novelties in elixirs and pessaries? Who would prevent venereal diseases, who knows the golden prospect from a protracted gonorrhœa, an obstinate stricture, a chain of suppurating buboes, or a crop of mucous patches? He can never have heard the crackle of a crisp greenback, who would advocate certified hospitals for the gratuitous treatment of these unfortunates,—vile, debauched, and prostitute though they be; for the most sanctimonious prater that the ways in which Divine Providence chastises sin should not be interfered with by man does not refuse to pocket the sinner's fee who objects to the chastisement.

A very little leaven affects the mass. Imbued with the tradesman's spirit, medical societies—some only, not all—have insensibly become little else than trades-unions, and, assembling ostensibly for professional improvement and the greater glory of the science of medicine, they make their shibboleth the criterion of professional fellowship. I foresee that this may be echoed back as a charge against this Academy; but the medical trades-union is not a lodge of masters of the craft, but a mere coterie of men who have learned by rote a creed they need not even understand so long as they swear by it. This, with a hieroglyphic M.D. on parchment, as unintelligible to the owner as his Latinized name done in German text is irrecognizable by him, entitles him to enter the most holy place, where all sit on the same level worshipping the same unknown God.

It is the huckster's trick to hide under the cloak of his reputable neighbor, that the latter may share the blow intended for the other. Anticipating, therefore, the charge that I am inveighing against medical societies indiscriminately, I desire to emphasize that I refer only to those bodies whose members are banded together after the fashion of mechanics' unions, by fee-bills prescribing how much shall be charged for administering a dose of castor-oil, dressing a sore, and extracting a baby, or rather watching a baby extract itself, and by formulized rules of behavior, rather than by that innate sense of honor and that rectitude of purpose, the outcome of

* The Medical Record, vol. xxvi. No. 3, p. 83.

culture, refinement, and education, which ought to characterize every reputable man who claims to be *doctus in medicinâ*.

Unfortunately, the degradation of our great science has not been retarded by its development. While in every country, and here as prominently as anywhere in the world, investigators are reaching one headland after another in unknown seas, and clearing away the undergrowth of ignorance that covers new lands for cultivation, the sciolist and charlatan still jabber their scanty jargon and display their rule-of-thumb methods. Is the profession bound to accept this rabble as part of it, or shall it repudiate them as unworthy its honor and dignities?

It is a fact that attempts at exclusion of this rag-tag and bob-tail—by requiring tickets of admission, certificates of qualification, testimonials of merit, to be presented at the gate of the temple—have failed of their purpose. Tickets are begged, borrowed, or stolen; certificates are forged; testimonials are wheedled from some benevolent master who cannot say "No." It is well enough to proclaim that a proper degree of medical intelligence shall be a requisite, and to insist upon preliminary academic training and systematic instruction in medical philosophy before mere medical handiwork. A few schools have undertaken this, but there are ninety-and-nine others which still grind out their smatterers to recruit the tribe of empiric tradesmen. State Boards of Medical Examiners, not trammelled by school affiliations and predilections, attempt, in some States, to arrest the overflow from unscrupulous college-mills; but their sieves are coarse, and only the rougher cobbles are arrested, and the stream that flows by is still a muddy one. A third barrier has been sought in medical societies, but, although some of these have boards of censors, who rigorously scrutinize every candidate's qualifications, others, as I have intimated, have taken their hue from the majority, and themselves become not much better than trades-unions. Shall, then, fellowship in this Academy be the *sine qua non* of professional reputableness? While I believe there are none here who have not won their spurs, there are too many *preux chevaliers* in the ranks for us ever to hope to have them wear our colors. I do not pretend that the mere possession of one degree more than another is a guarantee of competence, though the academic grades in Belles-Lettres and the liberal arts do mean something more than the empty pretentiousness of the more sonorous doctorate; neither will the additional brand of Oxon., Cantab., Harv., Y.C., U.P., A.M.C., or C.P.S.N.Y. serve any better to distinguish the sheep from the goats; for cultured men, graceful writers, profound thinkers, acute observers, and learned scholars are found in our profession, whom no degree can dignify, and whom no caudal alphabetics are needed to identify.

After all, the remedy is with the profession itself, and back we come to the point on the circle at which we started. Who constitute the profession? Is medicine a tri-unity of science, art, and trade? Are the scientific physician, the expert mechanician, and the plodding tradesman *fratres nobiles*, or are they distinct and demarcated by well-defined lines,—not metamorphosing one into the other like larva, pupa, and imago, but separable vocations? I begin to believe this inevitable. I have elsewhere ventured to suggest that the medical neophyte shall receive the degree of M.B. on leaving college, the statelier degree of M.D. being reserved for those who have proved themselves worthy of it. But if all colleges will not exact a literary preparative; if they will not graduate only bachelors, and reserve the doctorate for those of riper years, wider experience, and profounder research; if licenses to practise cannot be limited to the properly-qualified; if medical societies will not rigorously exclude every illiterate, ignorant, and incompetent applicant; if a sentimental objection exists in this free country to the doctrine that one man is not as good as another in medicine as in anything else, no matter whether he knows anything about it or not;—then the only thing left is for those who are content to stand on the tradesman's level to stand there for aye. But let those who look upon medicine as something else than a traffic in human misery, a means of self-aggrandizement at the expense of human suffering, have the courage of their convictions, and stand apart.

Is it arrogant and vainglorious assumption for you and me to refuse to recognize as a professional compeer a man who, having accepted the position of apothecary

in a public institution, protested he could not find any muriatic acid in the dispensary, with the bottle labelled "Acidum Hydrochloricum" staring him in the face, and showed his familiarity with the metric system by equivalencing grammes with grains; or that other who, not two months ago, signed a letter stating that he and a consulting friend, who had been called to a case of unmistakable suicidal narcosis, had not thought it their province to attempt any treatment in the absence of his official superior, and for six hours sat by and saw him sleep into death,—an instance parallel with one that occurred to me, some years ago, in consultation over an opium suicide, when the attending physician had been some hours trying to persuade the recalcitrant patient to take something, until the latter became too drowsy to argue longer? Must we take them by the hand and sit in solemn, owlish conclave with such men because they can flourish their regular M.D.? Then what should we do with that other who prescribed for a lady in Philadelphia—

℞ Sulph. quiniæ, gr. xx;
Strychniæ, gr. i;
Acidi sulphuric. F., 2½ oz.;
S. Coch. parv. (a teaspoonful) 4 times daily;

and was only saved from killing her and adding torture to the act of dissolution by the greater wisdom of the apothecary to whom it was sent to be compounded?

Who of you, whose wife and child go to a strange place, does not feel a greater dread of the unknown doctor than of the unforeseen disease they may encounter? There was comparative safety so long as the village medical bumpkin treated dyspepsy, wind-colic, and yaller janders with calomel and jalap or black draught; you had the satisfaction of knowing that the thing did not stay in you; but now that the great manufacturing drug firms are sending their pretty pink-and-white confectionery into every doctor-shop, however humble, you do not know what mighty and mysterious alkaloid may find its way into your penetralia to stay.

And this brings me to a very good starting-point in our proposed reform, by suggesting that there are beams in our own eyes that may profitably be removed. It may involve considerable sacrifice of personal consequence and some self-abasement to admit frankly that we do not know everything, that we cannot cure every disease, that there are problems in therapeutics we cannot solve off-hand, and in many instances we do not really know what the matter is, and that, despite the elegant polypharmacy of the day, we do not know what thing it is right to give. This will distinguish at once the physician of culture from the men who know everything and can cure anything, from cancer to the itch.

If, however, medical men are to be honest and say, "There is nothing the matter with you; you do not need any medicine," or, "I do not know what is the matter, and I will give you nothing until I do;" if benevolence and charity are to make them refuse the fee the poor woman and child cannot afford to pay, and they are to say, "Keep it to buy bread; you want no drugs;" if the exuberant growth of the Pharmacopœia is to be pruned down, and a warm bath and rest in a clean bed and quiet room, or exercise in the fresh air and sunshine and substantial food, are to be the routine prescriptions, and a few potent drugs are to be used, like surgeons' knives, only when we know where and with what to cut;—if all this be done, how can men who have made medicine their vocation expect to live?

In the first place, a higher standard, educational and professional, would greatly reduce the number of applicants for this calling, and the graduate would, in the second place, not, as now, have to hang out his sign and wait for the patients chance might throw in his path, but begin his career in some of the hospitals, dispensaries, and eleemosynary institutions, which should be multiplied until every sufferer too poor to pay can receive gratuitous attendance. But while the patients at such establishments ought not to pay, the medical officers attached to them ought to be well paid; and this is where and how I would have every young physician begin his professional life,—in the receipt of an "assured salary," an income sufficient to enable him to live honestly and reputably, which is all the army medical officer can boast whose officious intermeddling in the cause of suffering humanity has so excited the ire of his neighbor tradesman.

In recent years the practitioner who, from special aptitude or preference, who, having a soft, pliant hand and sensitive touch, or an ear recognizing shades of

tone in the rushing currents of blood and air, has limited his work to special classes of disease, has been looked at askance by many in the profession, as treading exceedingly close to the border-pale of recognition, and the little private hospital or dispensary he establishes, where the poor come for relief and his pupils cluster to learn, is denounced as an encroachment upon the field of general practice on which the young physician is to find subsistence. But why should not the wretched poor have the benefit of the highest medical skill and knowledge as well as the wealthy parvenu, who hires his doctor, however renowned, in the same spirit as he hires a coachman? What man owning a complex, intricate machine would intrust its repair to a novice in mechanics? Which of you will take his Jorgensen to the watchmaker who repairs his kitchen-clock? Why, then, place this human body—the most complex, intricate, and least understood of any mechanism ever devised—at the hap-hazard of some tyro in medicine? Which one of us does not shudder when he looks far back into his youth and recalls how blindly and recklessly he assumed the solemn responsibilities of this greatest and grandest of men's callings?

Let us, then, multiply and encourage the special wards and dispensaries until there shall be cliniques for eyes, ears, throats, lungs, and hearts; for skin, nerves, limbs, and abdomen; for venereal diseases and cancerous diseases; for consumptives, for paralytics, for the poor and the maimed, and the halt and the blind; and if there is not public spirit in the State to support these charities, then appeal to the churches in concert to assure the task, and undertake the great mission-work of making the blind see, the lame walk, and the dying revive. In this work medicine and religion can labor on common ground. There is no other avenue to the soul than through the body, and they who would care for the former must see that its earthly tenement is undefiled. Church sanitary work of the broad, unsectarian character I suggest would have this other result,—of making known the needy as well as the afflicted, the poor to whom food and drink will be wonder-working medicine. The light of medical knowledge makes many a hidden sorrow visible, and the doctor whose soul is not eclipsed by the round disk of a silver dollar looks upon the wan faces and flaccid limbs of the ill-fed and under-fed women and children he everywhere encounters as sadly as if they were seared by cancer or racked by phthisis.

The multiplication of endowed hospitals, asylums, infirmaries, dispensaries, and cliniques for treatment of the poor, whose necessities are properly certified by sanitary officials, magistrates, or church authorities, and of private hospitals and sanitariums for the rich, who can afford to pay, would give employment to a very large number of medical men, the older as guides and instructors, the younger as students and workers,—all equitably remunerated. Not only would they serve the people who now fly to every nostrum and panacea, but return a medical harvest, in the shape of exact statistics of disease, —now meagre and unsatisfactory. Every charitable institution would be a school of experimental medicine, in its justifiable sense, under the supervision of the highest medical authorities.

But there is a wider, equally useful, and just as necessary field for medical skill and intelligence in the still-to-be-established municipal sanitary service. Communities some day are bound to discover that prevention is cheaper than cure, and sanitary inspectors are bound to be in demand.

The Medical Record of August 9 very properly contests the assumption of *The Sanitary News*, "that the most efficient and reasonable sanitary work is accomplished by men outside the medical profession," and pertinently asks, "Will not our excellent contemporary *The News* now publish some letter from A Plumber to a Young Doctor, for example, telling him how to avoid typhoid fever, cholera, smallpox, etc.?" The popular idea of the physician as a cormorant of fees is speakingly illustrated when a journal of the high literary and scientific character of *The Sanitary News* editorially says, "The really useful and valuable sanitary work which conserves the public health is done by these same 'perpetrating' architects and by plumbers, when they design and execute those measures which *cheat the physician out of his bill* by preventing the causation of disease." Happily, the profession vindicates itself. The ablest, most zealous, most enlightened advocates of sanitary reform are themselves able, zealous, and enlightened physicians. The

time is not distant when sanitary inspectors will be demanded in every city, town, and hamlet. They should be found at every railway-station, and at every mercantile entrepôt, and every factory and market-place, at every school and church and theatre, and overseeing every dairy, bakery, butcher's stall, and grocer's shop; and ninety thousand physicians can have no better or more appropriate and honorable employment than enlisted in such service. There is not a city in this country in which to-day the fines for violations of even existing health-regulations would not more than suffice to defray the expenses of a well-remunerated sanitary establishment, and an efficient sanitary service cannot be a cheap one, nor ought the attempt to be made to conduct it on a parsimonious plan. Competent inspectors can only be secured and interested in their work by receiving adequately compensative salaries. In my opinion, too, the dignity of the office of the family physician would be enhanced if he likewise were salaried and paid as the sanitary adviser and counsel of each household, his income being determined by the size of his clientage, and not by the fortuitous occurrence of a case of typhoid, or an epidemic of measles, welcomed for their greater money value.

The poor provided for; the young practitioners serving at hospitals, dispensaries, and cliniques; the mass of the profession doing honorable, legitimate yeoman service in caring for the health of the community, there will be left ample employment for the elders,—the experienced physician, the skilful surgeon and accoucheur, the dexterous special operator,—to whom naturally will fall those greater rewards to which greater ability and larger practical acquaintance justly entitle them.

There is truth enough in medicine for us to eliminate humbug and leave it to the quack, who will thrive as long as credulity is an element of human nature. We need no alchemic parade of many-thousand-paged dispensatories; a modest volume will hold our therapeutics. Let our quartos be for the facts of anatomy and biology. The natural history of man is not all unfolded; the natural history of disease in its myriad protean forms to be yet written will fill more tomes than one can write or generations read. There are laurel wreaths for the investigators,—who will make disease impossible,—which they can wear without blushing, as he must who hears himself lauded for marvellous cures to which he knows he has no title. Let the trader in cure-alls sound his wares in the illegitimate fashion of the undisguised quack or by the legitimate method of the regular charlatan. The nurse, the midwife, the prescribing apothecary, the cow-leech, and the corn-doctor, are petty tradesmen of the same calibre with them. Let us repudiate the assumption that a shrewd knowledge of the sick-room is all that is required to make a doctor in medicine, and insist upon our claim that there is no intelligence too bright, no application too profound, no industry too severe, to be devoted to the study of medicine, in which, as Professor Young said at Philadelphia of the study of the heavens, "the human intellect finds most invigorating exercise and most nourishing and growth-making aliment." To those who would give it narrower scope let us be able to respond, "Not of that ilk."

In the republic of letters every scrivener is not a senator, but the *aristoi* wear their laurels neither by birthright nor by letters-patent. Why should any dolt and ignoramus be veneered by a piece of cabalistic sheepskin into a doctor in medicine? If it be undemocratic in this country, where theoretically all men are born free and equal, to recognize impassable classes of practitioners, as in England; or if a baccalaureate probation cannot be exacted of every graduate before he has a right to wear the doctor's toga; if societies will not refuse fellowship to the illiterate possessor of a diploma, who has neither the ability nor ambition to rise in his vocation above the tradesman's level, let us at least proclaim our belief that there is a higher medicine than leech-craft, and uphold its honor and dignity by not countenancing, by act or word, those who have had part in its degradation.

PRESENCE OF BACILLI LEPRÆ IN ANÆSTHETIC LEPROSY.—Dr. Arning, at present in Honolulu (*Virchow's Archiv*, vol. xcvii., 1884), excised portions of the ulnar nerve in two cases of pure anæsthetic leprosy, and found bacilli lepræ in the connective tissue between the nerve-fibres. This is the first time that the presence of bacilli in the pure anæsthetic form has been demonstrated.—*London Medical Record.*

REPORT ON MEDICAL CHEMISTRY.

BY WM. H. GREENE, M.D.

CHEMISTRY OF THE URINE.

THE FERMENTATION METHOD for the estimation of glucose in urine has been made the subject of a careful study by Worm Müller, in conjunction with J. Hagen, who recommend a titration with Knapp's solution before and after the addition of yeast. The difference in the results is capable of indicating a proportion of glucose as small as 0.05 per cent. The reduction which takes place after fermentation is due to reducing agents other than glucose, and cannot be neglected in urine containing only 0.04 to 0.05 per cent. of glucose. Besides this, a small quantity of the glucose, equivalent to 0.01 to 0.02 per cent. of the total proportion present, is destroyed by the yeast.

ROBERTS'S METHOD for the estimation of glucose, by the difference in density before and after fermentation, answers well for urine rich in glucose, but is untrustworthy when the proportion is below 0.5 per cent. In normal urine to which a known quantity of glucose has been added the results obtained are always too high when the difference in specific gravity is multiplied by Roberts's factor (.001 difference = 0.23 per cent. glucose) or Manassein's factor (.001 difference = 0.219 per cent.). Fermented diabetic urine has a lower specific gravity than would result from the fermentation of the glucose. On the contrary, urine containing but little glucose often gives too low results by Roberts's method.

A MODIFICATION OF THE METHOD FOR THE DETECTION OF GLUCOSE BY FEHLING'S SOLUTION has been proposed by George Buchner. In many specimens of urine containing glucose, heating with Fehling's solution produces only an opalescent yellowish-red coloration, and no red precipitate of cuprous oxide is formed. This result is exceedingly unsatisfactory, as the presence of glucose then appears doubtful. In such cases the urine should be treated with an excess of cupric sulphate solution (one to ten), and heated to boiling. A grayish-green precipitate then separates, and is separated by filtration after the liquid has cooled. On now adding a solution of potassium hydrate or some Fehling's liquid to the filtrate, an azure blue color is produced, and red cuprous oxide separates on boiling, even when the urine contains only a minimum proportion of glucose. In all cases in which the ordinary application of the test, as well as successive additions of cupric sulphate in alkaline solution, gave ambiguous results, G. Buchner obtained by his method the most decisive glucose reaction. The previous separation of creatinin by zinc chloride is troublesome and wastes time; the first addition of the copper sulphate solution causes the separation of uric and phosphoric acids, and removes the creatinin by which the reduction of the cupric oxide by glucose is impeded.

POTASSIUM CRESOLSULPHATE has been obtained by L. Brieger from fresh urine. This substance was precipitated first with neutral and then with basic lead acetate, and filtered; the filtrate was freed from lead by hydrogen sulphide, evaporated on a water-bath, and placed in a vacuum. The crystals which separated after a time were recrystallized from hot absolute alcohol, and identified as the before-named salt.

A NEW REAGENT for the examination of urine has been proposed by P. Ehrlich. It is a very dilute solution of *paradiazobenzolsulphonic acid*, which may be first prepared in the crystallized state and dissolved in water, or can be produced in the test-liquid by adding a few fragments of sodium nitrite to an aqueous solution of sulphanilic acid acidulated with from six to ten per cent. of pure nitric acid.

When normal urine is treated with this reagent there is only a faint change of color, and it is altered to orange by the addition of ammonia or potassium hydrate. In certain diseases, on the contrary, the reagent causes the urine to assume a carmine or purple-red color, the shade of which can be readily appreciated by an examination of the froth formed after the liquid has been shaken. This reaction has been observed in pulmonary phthisis, and constantly in typhoid and scarlet fevers. It is rarely produced by the urine of patients suffering from pneumonia or diphtheria.

The coloration is probably caused by pyrocatechin and other phenolic compounds which may be present in the urine, but F. Penzold has recently shown that the paradiazobenzolsulphonic acid reagent may be colored red by many other bodies in presence of alkalies. Among these are acetone, lactose, saccharose, and glucose.

Ptomaines or Analogous Compounds have been obtained from urine, as well as from other products of the organism, fresh and putrefied, by A. G. Pouchet. By precipitation with tannin and dialysis, these products were classified as non-dialysable liquids and readily dialysable crystals. The liquid product so obtained from urine has a composition responding to the formula $C^3H^5NO^2$; it is very alterable, and is resinified by hydrochloric acid. The crystallizable portion seems to have the composition $C^7H^{12}N^4O^2$ or $C^7H^{14}N^4O^2$, and yields a definite chloroplatinate. These products are related to the oxybetaïnes, and are quite poisonous.

Urochloralic Acid is the name given by Von Mering and Musculus to a levogyrate acid which was extracted by them, in 1875, from the urine voided after the ingestion of chloral. Richard Kulz recommends the following method for the preparation and identification of this compound. The urine is agitated with a mixture of ether, alcohol, and sulphuric acid, and the residue left on the evaporation of the extract so obtained is precipitated first with neutral and afterwards with basic lead acetate. The last precipitate is decomposed by hydrogen sulphide, and, after the lead sulphide and excess of hydrogen sulphide have been removed, is neutralized with barium hydrate, evaporated to crystallization; the barium salt is decomposed with dilute sulphuric acid, and the filtered liquid is evaporated to a syrup at a low temperature, and then dried in a desiccator; the dry mass is exhausted with hot ether, and the urochloralic acid crystallizes from the ether extract.

The Occurrence of Large Quantities of Indoxylsulphuric Acid and Skatoxylsulphuric Acid in the Urine in diabetes mellitus has been observed by J. G. Otto. In one case, in which, by Jaffe's method, considerable quantities of indigo, amounting to 0.1617 gramme per day, could be prepared from the urine, Hoppe-Seyler's modification of Baumann and Bruger's method, to ten litres of urine, enabled the separation of potassium indoxylsulphate in substance. In another case concentrated nitric acid colored the urine red, and the addition of ferric chloride produced an intense violet-red or purple color. From eleven litres of this urine 0.8 gramme of pure potassium skatoxylsulphate were obtained. The alcoholic extract of the evaporated urine was concentrated and allowed to remain in the cold until a deposit formed; this was removed, and the liquid was treated with a saturated alcoholic solution of oxalic acid and filtered. The filtrate was rendered slightly alkaline with alcoholic potassium hydrate, again filtered, and the liquid concentrated on a water-bath. The salts which separated were removed by filtration, and the evaporation continued until the residue was syrupy. This was then dissolved in warm absolute alcohol, from which the potassium skatoxylsulphate crystallized on cooling. An analysis of the substance, recrystallized from boiling alcohol, gave figures corresponding to those required by theory, and this compound is probably the skatol combination previously observed by Baumann in urine.

Peculiar Constituents in Diabetic Urine.—Hallervorden has observed increased quantities of ammonia in the urine of many cases of diabetes mellitus, and Stadelmann isolated from the urine in one such case *notable quantities of crotonic acid.** According to O. Minkowsky, however, the crotonic acid does not exist already formed in the urine, but is produced from the β-oxybutyric acid which this investigator has extracted from diabetic urine. Oxidation of this substance yields acetylacetic acid, and the existence of this substance and of the acetone, which have been noticed from time to time by various experimenters, is probably to be attributed to the previous existence of β-oxybutyric acid.

Copaiba Urine.—The urine voided after the ingestion of copaiba balsam assumes a red color on the addition of hydrochloric acid, and gives an absorption spectrum showing three bands, one of which—in the blue—disappears on the application of heat, and at the same time the fluid acquires a violet color. Bleaching-powder, as well as tincture of iodine, accelerates the reaction, which is attributed by Brix to a terpene contained in Maracaibo balsam (Gurjun balsam), and the urine excreted after its ingestion yields the same results (C. le Nobel).

Determination of Total Nitrogenized Constituents of Urine.—Th. Lehmann has investigated the application to urine of Kjeldahl's method for the deter-

* See Medical Times, vol. xiv. p. 708.

mination of the total nitrogen of animal substances. By this method the urine is evaporated with sulphuric acid, and maintained for a time at a temperature somewhat below that of the boiling-point of the acid, powdered potassium permanganate being added in small quantities. All of the nitrogen is thus converted into ammonium sulphate, and by the addition of sodium hydrate and distillation in a current of steam the ammonia is driven out and its quantity determined by any of the usual methods. Estimations by this method gave results closely corresponding to those indicated by the total urea, uric acid, hippuric acid, etc.

A Synthetical Colloid Body Closely Resembling Albumen has been obtained by E. Grimaux by the action of phosphorus pentachloride on metamidobenzoic acid. After heating the mixture for an hour, the mass is treated with boiling water until the residue becomes a white, friable powder; this is moistened with ammonia; it swells and dissolves slowly, forming a liquid which filters with difficulty. After filtration it is evaporated in vacuo; it then thickens to a diaphanous jelly, and dries to a yellowish, translucid mass, which is tasteless and odorless and closely resembles the albumen of serum. The colloid so obtained swells and dissolves slightly in cold water, but is freely soluble in hot water, and its solutions can be heated to boiling without alteration. If the liquid be evaporated on a water-bath the appearance of the residue is not different from the original substance, but it is insoluble in water. Grimaux has published a full description of the reactions of this interesting body, and the following comparison of its properties with those of albumen:

A One-Per-Cent. Solution of Albumen	*The Amidobenzoic Colloid*
Is not coagulated by boiling; becomes opalescent.	Is not coagulated by boiling; becomes clouded after a few minutes' boiling.
Is precipitated when hot by common salt, calcium sulphate, magnesium sulphate, ammonium chloride.	Identical.
Is coagulated by heat after saturation by a current of carbon dioxide.	After the addition of sodium chloride insufficient to produce coagulation, is coagulated by heat after saturation with carbon dioxide.
Is not precipitated by acetic acid.	Is precipitated by acetic acid.
Is precipitated by nitric acid in the cold.	Identical.
The precipitate is soluble in ammonia, insoluble in sodium phosphate.	Identical.
Is precipitated by tannin and salts of mercury.	Identical.
With cupric sulphate, gives a precipitate which dissolves in potassium hydrate with a violet color.	The same, but the alkaline solution is rather blue than violet.
Is still soluble in water after evaporation in vacuo.	Identical.
Is insoluble after evaporation on water-bath.	Identical.
Nitric acid colors the precipitate yellow.	Identical.
Properties of Solutions which have been Heated.	
Precipitated in the cold by acetic acid.	Identical.
The precipitate dissolves easily in an excess of acetic acid.	Precipitate dissolves with difficulty.
Precipitated in the cold by carbon dioxide.	Identical.
The precipitate formed by carbon dioxide in the cold is redissolved on passing a current of air.	Identical.
The presence of sodium phosphate prevents precipitation by carbon dioxide.	Identical.

The conclusion of Grimaux is that physiologists are in error when they assert that the substances which are of the highest importance in the functions of life, the albumines, do not present the character of chemical combinations. Contrary to such assertions, his researches prove that the albuminoid bodies owe their complex reactions to the fact that they are colloidal bodies.

N. Simanowsky and C. Schoumoff have made some experiments on *the influence of*

alcohol and morphine on physiological oxidation. They have applied, as suggested by Sieber and Nencki, the oxidation of ingested benzol to phenol as the measure of the oxidation taking place in the system. The elimination of phenol lasts from two to four days. A dog which normally excreted from 0.2831 to 0.2483 gramme of phenol for every gramme of benzol ingested, eliminated only 0.1649 gramme after the administration of 0.3 gramme of alcohol per kilogramme of weight. An increase of the alcohol to 3.1 grammes per kilo of weight reduced the phenol eliminated to 0.1256; on the contrary, the administration of 0.02 gramme of morphine hydrochloride per kilo increased the phenol to 0.309 gramme. Another dog eliminated from one gramme of benzol 0.1596 to 0.1696 gramme of phenol; after the administration of two grammes of alcohol per kilo of weight, the excretion of phenol was only 0.0772 to 0.0731 gramme, but after doses of 0.01, 0.03, and 0.04 gramme of the morphine salt per kilo, the excretion of phenol was increased to 0.2228, 0.2131, and 0.2228 gramme. In a man of twenty-seven years, after the ingestion of a little more than two grammes of alcohol per kilo of weight, the quantity of phenol eliminated from the oxidation of two grammes of benzol fell from 0.8205 to 0.3301 gramme. It seems, then, that morphine increases the oxidizing powers of the system, while they are correspondingly depressed by alcohol. Alcohol appears also to diminish the quantity of urea excreted, but the elimination of urea is no measure of the oxidation going on in the organism; constriction of the air-passages, which increases the excretion of urea, diminishes the quantity of benzol which is oxidized to phenol. In neither man nor dogs could any more than traces of the ingested alcohol be detected in the urine. We may remark that these results of Simanowsky and Schoumoff are in harmony with the known thermic effects of alcohol.

The Use of Plaster Filters for the Sterilization of Fermentible Liquids has been criticised by P. Cazeneuve. These filters were first employed by Pasteur for the separation of microscopic organisms from the liquids in which they may be suspended, and have been largely used for *cold sterilization.* They are made by simply allowing plaster mixed with water to harden in a funnel; after drying and subjecting to a proper degree of heat, the funnel is adapted to the cork of a bottle in which a vacuum can be made. Under the pressure of the atmosphere, the liquid is forced through the pores of the plaster, while the solid particles, no matter how small they may be, are retained. The plaster is usually mixed with asbestos, and the filters are prepared with great care. The small quantity of calcium sulphate dissolved out by the liquid has been found to exercise an antiseptic action, and, as Miquel has stated, porous porcelain filters are preferable for this reason.

Cazeneuve now shows that the plaster retains albuminoid matters: milk, blood, and bile, diluted with ten times the volume of water to render filtration more rapid, are completely deprived of albumen by passing through a plaster filter. If the filtration be continued for a sufficient time, however, the pores of the filter become saturated with the albumen and allow albuminoids to pass, but the filtration is slow and difficult. In the same manner an albuminous urine gave up all of its albumen to the filter. The plaster acts chemically, for it forms combinations with certain albuminoid substances. The action of plaster on legumine and on the albumen of barley is well known. At the same time, however, the plaster acts mechanically by its capillary structure, and removes from the liquids the colloids which they hold in solution.

The method of cold sterilization which is desired must leave the albuminoid matters in the liquid, for they are necessary to the development of certain microbes. In this respect plaster filters are faulty. They are open, moreover, to a more serious reproach: they retain the soluble ferments,—that is, the diastases. When it is necessary to decide whether a fermentative liquid owes its activity, perhaps its poisonous properties, to an organized being or to a chemical principle such as diastase, the separation of micro-organisms by plaster filters is essentially at fault. The diastase of sprouted barley, the myrosin of white mustard, the synaptase of bitter almonds, pepsin, and the diastase produced by the *torula urinæ* are all retained by plaster filters, as proved by numerous experiments.

The consequences of these results are important in the theory of fermentations

and of the virulence of fermenting liquids. The question whether a micro-organism acts by its own functions, ill defined as these may be, or, secondarily, by reason of a chemical compound secreted by it, in which case the action becomes chemical or physiological, cannot be decided by experiments in which plaster filters are employed. These criticisms apply to Pasteur's celebrated observation on the bacteria of *charbon*, for he employed plaster filters for the separation of the bacteria from the blood. The filtered liquid was no longer virulent, but whether the virulence is due to the bacteria or to a poison secreted by the bacteria is left in doubt, for both are retained by the plaster.

M. Cazeneuve states that porcelain filters are not open to this objection to those of plaster, and in this he is confirmed by M. Armand Gautier, who publishes the description of a new filter of unglazed porcelain, in which all of the joints are made with a fused boro-silicate of lead. With these filters M. Gautier claims to have obtained perfectly satisfactory results.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY HOSPITAL.

SERVICE OF WM. PEPPER, M.D., LL.D.,

Provost of and Professor of Clinical Medicine in the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M.D.

EPILEPSY.

GENTLEMEN,—This little girl has been before you on one or two occasions. Let me recall to your minds the more important features in her history. She is 10 years of age, born of healthy parents, with no inherited morbid tendency, and lives in a healthy neighborhood. Up to the age of five years she was apparently healthy, but at this time it was noticed that she was "nervous" when her attention was strongly fixed. There is no history of severe sickness or other cause to account for this. Shortly after this it was noticed that the child began to have falling-spells, and these would sometimes recur as often as two or three times a day, and at no time did she go a week without an attack. In these seizures she would fall to the floor if there was no one at hand to support her, and she evidently lost consciousness for the moment, for she would assert that some one had thrown her down. There was no general convulsion, but for a few minutes there would be trembling of the hands. She did not froth at the mouth or roll the eyes, but after the attack had passed she became very red in the face.

She was brought to the hospital four months ago. At that time she was having the spells very frequently, and the mother could not trust her out of her sight. Her memory was also much impaired.

The story of this case is one of apparently essential epilepsy. No peripheral cause can be found for these attacks. The child has no heart-disease; there is no history of an injury or of a sudden shock of any kind, but gradually, without apparent cause, she at the age of five years began to have these attacks, which continued to increase in frequency until four months ago.

At that time, learning that the girl had been under the care of the family physician for some time, I concluded that the bromides had been thoroughly tried. The child was exceedingly feeble; she would drop down on the slightest exertion, and many of the falls were undoubtedly the result of muscular prostration and debility. There was also to a remarkable extent a want of mental activity. The child was listless, and her memory was rapidly failing. Concluding then that the bromides had been used, I considered it useless to push them. I thought it better to direct attention to hygiene, diet, the administration of tonic remedies, and trust to the development of the system, rather than attempt by specific remedies to coerce the manifestations of the disease.

I ordered a properly-regulated diet and the use of a simple solution of the phosphates of soda, lime, and iron in an excess of dilute phosphoric acid. The child had no other treatment.

The mother reports that there has been decided improvement. The attacks do not recur so often, a week frequently intervening between the attacks. The disease is, however, far from being checked, but we are encouraged to persist in the plan of treatment adopted. In the mean time the child will be kept from school, the mother teaching her at home.

GASTRALGIA.

This man, a farmer, aged 39 years, has been sick for two years. His principal complaint is of pain in the left side. He has lived in a healthy locality, and has never had chills and fever. The pain begins in the left side and runs back to the left shoulder-blade. If he eats too much he suffers, but the kind of food taken does not appear to influence the pain. An ordinary meal does not make the pain worse, and eating sometimes takes away the bad feelings. Active exercise or riding over a rough road is apt to bring on the pain. The appetite is fair. The bowels are sometimes constipated, but as a rule he has diarrhœa about twice a week, there being two or three loose stools, but these contain no blood. He weighs one hundred and fifty pounds. His best weight was one hundred and sixty-two pounds, but during the summer he goes as low as one hundred and forty pounds.

Let me here refer to this matter of variation of weight. Many persons will be met with who have a wide range of what may be called normal weight. I never like to see this symptom, for it seems to me that those persons who lose flesh so rapidly cannot be made of very good stuff. A person whose flesh is solid and who is living a correct life should maintain pretty nearly the same weight summer and winter, varying perhaps from three to five pounds. Persons will, however, be found whose weight varies twelve or fifteen pounds at different periods of the year. With such persons I have observed that sickness goes hard; on the other hand, loss of weight in them is not to be regarded as of such serious moment as it would be in a person who was thoroughly in training and whose flesh was solid and well organized.

In reference to the pain complained of, when this pain is in the right side, we naturally suspect some trouble with the liver, —a gall-stone in one of the smaller ducts or in the gall-bladder; some congestion of the liver, causing dragging on the suspensory ligament, or irritation of the capsule of the organ. When the pain occurs on the left side, we think of the spleen, pleura, and heart, and when, as in this man, the pain associates with some shortness of breathing and overaction of the heart, we are apt to think more particularly of the heart. Examination of the heart shows it to be perfectly normal. There is no enlargement of the organ, no displacement of the apex-beat, and the valvular sounds are free from murmur. Neither is there any evidence of chronic pleurisy. There is good respiratory murmur and resonance over the left side. Examination of the spleen shows that the organ is not enlarged, and the man has not lived in a malarious district.

Before satisfying ourselves that this is merely a neuralgic trouble (possibly a form of gastralgia), some obscure conditions must be thought of. One of the most insidious of these, and one against which we should be continually on our guard, is caries of the spine. Caries of the anterior surface of the vertebræ constantly reveals itself by pain and distress in the neighborhood of the spinal column. Many cases of sciatica or intercostal neuralgia will be found to be due to caries of the anterior surface of the vertebræ, and the diagnosis should not be made until a sudden increase of the symptoms, with some numbness and failure of power in the lower extremities or the appearance of an angular projection, calls attention to the real cause of the trouble. You will do well to be on your guard against the occurrence of this obscure lesion. Aneurism of the descending aorta is another condition to be excluded.

There is no tenderness along the spine, neither is there any projection of the vertebræ, and jumping does not cause pain. No pulsation, thrill, or abnormal dulness can be detected. Caries of the spine and aneurism may therefore be excluded.

You observe that the pain is described as occurring in the right side and over the stomach; it is not markedly affected by eating, although radishes and some other articles make it worse, and it is worse when the stomach is empty than it is after an ordinary meal. It is associated with evidence of derangement of intestinal digestion, as shown by flatulence and irregular action of the bowels, sometimes constipation and sometimes transient attacks of diarrhœa. Having excluded the graver causes for this pain, we must conclude that it is neuralgic and occupies the stomach, and therefore a form of gastralgia.

As to the cause of this, the family history is good, and he has had good health until this affection developed. He does not use liquor or tobacco; he has not been

overworked, but has gotten into the habit of eating his meals hurriedly. The gastralgia has probably been brought on by this rapid eating.

In the treatment of gastralgia the regulation of the diet is the chief element. The stomach is rarely able to receive and handle enough food in three meals to support the system; consequently it is important that such patients should take more than three meals in the twenty-four hours.

Again, the stomach is so hyperæsthetic and the mucous membrane so irritable that unless some digestible substance is in the stomach the acid juices are apt to excite pain, and hence the pain is more marked when the stomach is empty, and the ingestion of food affords relief; so that for this purpose, also, it is desirable to give food oftener than three times a day. Meals of smaller amount, and of extremely simple character, and at shorter intervals, is the rule for the nourishment of gastralgic patients.

The character of the food requires very close attention. In general, it will be found that milk is one of the best ways in which to give nitrogenous and albuminoid food. The starchy foods are, as a rule, well borne, particularly because they do not require much gastric digestion, being digested, as you know, by the salivary, intestinal, and pancreatic fluids. At times, however, the starchy foods lead to the development of secondary acids in the stomach, in which case it becomes necessary to diminish the amount of starch allowed and increase the amount of skim-milk, the patient being practically placed on an exclusive milk diet for a certain length of time. Alkalies are often desirable, and lime-water mixed with the milk is a convenient way of administering these.

I shall recommend for this man the following dietary:

Breakfast. — Soft-boiled egg, oatmeal, bread and butter, and milk with lime-water. Between breakfast and dinner, a glass of milk and lime-water.

Dinner.—Potatoes, bread and butter, milk and lime-water, but no meat. Between dinner and supper, a glass of milk and lime-water.

Supper.—Mush and milk, with milk and lime-water to drink.

In selecting the remedies to be associated with this diet, you will be governed by your appreciation of the state of the mucous membrane more than by anything else. If there is no evidence of gastric catarrh, if there is simply the hyperæsthetic neuralgia and anæmic condition of the stomach, iron, arsenic, and belladonna may be given at once with confidence, the stomach being sheathed with bismuth taken at proper intervals after eating. Under such circumstances, a pill containing the following might be given:

℞ Quiniæ sulph., gr. j;
Acidi arseniosi, gr. $\frac{1}{50}$;
Pil. ferri carb., gr. j;
Ext. belladonnæ, gr. $\frac{1}{10}$.
M. et ft. pil. no. 1.
Sig.—To be taken after food, three times a day.

Any of the vegetable salts of iron may be substituted for the pill of the carbonate. In addition to this, ten grains of bismuth should be given two hours later, to protect the stomach when most empty.

If there be a catarrhal condition of the mucous membrane, as shown by a coated tongue, distress in the stomach, in addition to the paroxysmal pain and evidences of dyspeptic trouble, we are obliged to adapt our remedies to this condition, postponing the use of anti-neuralgic remedies until the inflammation of the mucous membrane is relieved. In such cases bismuth with pepsin, dilute mineral acids, carbolic acid, and salts of silver become exceedingly valuable for their antacid, sedative, and alterative properties.

For this patient, having directed a careful diet with an alkali, we shall order minute doses of nitrate of silver with belladonna.

Two weeks later, the patient reported much improved, and the pill of quinine, arsenious acid, and iron above given was substituted for the nitrate of silver, the same diet being continued.

Treatment of Intestinal Hemorrhage of Typhoid Fever.—At a recent clinical lecture, Professor Da Costa exhibited specimens from a case of typhoid fever in which death had occurred from peritonitis, with three recent perforations of the bowel. The patient four days before his death had had a profuse intestinal hemorrhage. The distinguished teacher took the opportunity of endorsing the ergot treatment of the hemorrhage, but insisted upon the importance of following it up with decided doses of opium in order to prevent perforation or to limit its effects.

TRANSLATIONS.

THE MEDICAL TREATMENT OF PULMONARY CAVITIES.—Professor M. Trastour, of Nantes, concludes an interesting clinical paper upon the medical treatment of vomicæ in the lungs with the following practical deductions. Given a case, tuberculous or not, which has had and still has pus in the lung, the pleura, or mediastinum, which pus is evacuated through a vomica, and sometimes through thoracic fistulæ,—a case in which there is no urgency, necessity, nor opportunity for thoracentesis, aspiration, or resection of the ribs,—what is the medical treatment to prescribe? This query he answers as follows: *First indication.* The suppuration can only cease if the walls of the pus-cavity retract sufficiently for cicatrization; for this it is required, on one hand, that the lung shall dilate, on the other, that the thoracic wall shall yield and become deformed. In some cases this deformity is very marked; and such depressions at one point or over one side of the chest are sometimes both striking and instructive, as noticed and figured by Laennec. The leaning to the affected side, the dropping of the shoulder, the diminution of the anterior and posterior muscular layers of the thorax in the young, a tendency to lateral deviation of the spine, and prominence of the scapulæ and sometimes the compensating fulness of the opposite side of the chest, were all noted by him also.

Chronic pleurisy, thoracic abscess, and tubercular cavities may all produce deformities of the chest in subjects that are still young. The chest, said Laennec, must retire to make up all of that which the enfeebled lung is unable to furnish by dilating. The first indication of medical treatment of vomicæ is, therefore, to favor the sinking of the chest-wall until cicatrization can occur, while diminishing as much as possible the inevitable deformity. To accomplish this what will be necessary?

First, empty carefully the cavity as completely and as frequently as possibly can be done. For this inversion has been practised with good results. Prescribe and obtain the frequent practising of deep inspirations, made methodically, in order that the lung may be made to expand.

Secondly, the disposition to the formation of pus must be combated; for which iodine preparations are recommended.

The third indication is to prevent emaciation by giving a liberal, easily-assimilated diet.

Fourthly, auto-infection must be guarded against by antiseptics and disinfectants. A glycerin spray, with or without carbolic acid, is very grateful to the patients.

Fifthly, revulsives are useful over the affected area of the lungs.

In the sixth place, and finally, he insists on the value of living in the country and of breathing pure air. He recommends to those suffering with empyæma that they should breathe the air of the fields, or even, as an experiment, to try that of the sea-shore when a favorable opportunity presents.—*Bull. Gén. de Thérapeutique.*

IODOFORM IN TUBERCULOUS ULCERATION OF THE LARYNX.—Drs. Kussner, of Halle, and Frankel, of Berlin (*Journal Méd.-Chirurg. de Buda-Pesth*), highly recommend the employment of iodoform in the laryngeal ulceration of phthisis. The former uses a ten-per-cent. solution in glycerin, applied by a small piece of cotton, and also an inhalation three or four times a day of the following:

℞ Iodoformi, one gramme;
Spts. vini, ten grammes;
Aquæ, fifty grammes. M.

This can also be used in the atomizer. It is claimed that under this treatment the ulcers clean off and proceed to repair, but the general condition is also much improved: (1) the cough is reduced and expectoration diminished; (2) the hectic fever is reduced.

Dr. Kussner, on the contrary, has not found that the physical signs of phthisis are modified, but, although iodoform cannot be regarded as a specific, some cases are much benefited, because it retards the evolution of the disease and causes the disappearance temporarily of some of the symptoms.—*Bull. Gén. de Thérapeutique*, October 15.

THE USE OF ANTIPYRINE HYPODERMICALLY, it is claimed, causes neither general nor local inconvenience (*Centralblatt für der Gesammt. Therapie*). The best solution for this method of administration is said to be one gramme of antipyrine in fifty centigrammes of water, dissolved with the aid of heat.

MEDICAL TIMES.

PHILADELPHIA, NOVEMBER 15, 1884.

EDITORIAL.

EXPERT MEDICAL WITNESSES.

OF medical experts upon the witness-stand it might almost be said, repeating Whately's criticism of Whewell, that "Science is their forte, omniscience their foible," for your medical witness usually expresses his opinions with as much assurance upon purely legal questions as he does upon medical matters, assuming at once the functions of counsel, judge, and jury. This unfortunate propensity is often utilized by counsel in order to discredit the testimony of the witness upon other and purely scientific questions. We were pleased, however, to notice, during a recent criminal trial in this city, that Prof. Wood, when upon the witness-stand, recognized this distinction; and when asked "If he thought the prisoner responsible for the deed?" he at once referred the question of technical responsibility to the court itself, where it really belonged.

To show the status of the expert witness, we may also note that during the same trial an officer of the prison, not a medical man, was put upon the stand to testify concerning the mental state of the prisoner at the time of committing the murder, and his years of experience with criminals were ingeniously paraded by counsel, obviously, in order to put him before the jury in the same light as the medical witnesses whose testimony he was brought forward to oppose. Apparently the non-medical testimony was sufficient to outweigh that offered by the medical experts, because the jury brought in a verdict of guilty of murder against the poor criminal, although he was believed to be insane by competent medical witnesses, and had been so pronounced after more than one careful examination.

It is quite time that some change had been made in our prevailing methods of taking medical testimony. The facility with which many physicians can be induced to go upon the stand in order to directly oppose the testimony of their brother-physicians brings discredit upon medical science and disgrace upon the profession. It is this practice which has led a judge to declare slightingly that "doctors could be obtained to swear to anything," and which has especially confused the public mind upon great medico-legal questions, such as how far legal responsibility may be affected by different degrees of mental unsoundness. Since medical questions must occur, and since they can only be answered by physicians, it will continue to be necessary to have medical experts to instruct the court. We are entirely opposed, however, to the present loose method of selecting them, and particularly to their being pitted against each other by opposing counsel, to the great scandal of the profession. A change in the practice might be made which would be more in keeping with the dignity of the profession, and would aid, or certainly not retard, the course of justice. Instead of wrangling openly in court, let the experts selected by the counsel upon both sides, perhaps with the addition of one appointed by the judge, form a medical commission, to whom purely medical questions shall be referred for consideration and decision in private session, the responsibility of acting upon their conclusions being left to the court. If, for instance, it be in a case of supposed insanity, the commission would communicate simply the result of the medical examination to the court, leaving the degree of responsibility and the question of punishment where it belongs.

The appointment of medical examiners, in place of that obsolete functionary

known as the coroner, would greatly facilitate the solution of such questions, to the great satisfaction both of the profession and the public. We commend this question to the medical societies for agitation.

GLOSSO-LABIAL PARALYSIS.

MODERN thought and research drift more and more to the position that the affection described by Duchenne as glosso-labial paralysis, and long supposed to be distinct, ought to be stricken from the list of diseases. In its typical form it is certainly only a localized chronic poliomyelitis, a mere variety of chronic muscular atrophy, in which the gray portion of the upper segment of the spinal cord—*i.e.*, the medulla oblongata—is especially attacked. It may exist by itself, or it may be associated with symptoms of palsy, due to poliomyelitis, in other parts of the body. In the latter case the medulla may be the first part of the cord invaded, the disease extending downwards, or the lesion may progress upwards and the medulla show the latest change. In a very interesting case recently shown at the clinic of Prof. H. C. Wood, the first symptoms were perceived by the patient in the mouth region, and subsequently the cervical cord became profoundly affected.

To grant these labio-glossal paralyses a separate state in our classification of disease would logically require similar treatment for cases of progressive muscular atrophy in each part of the body, since any spinal region may be attacked alone or separately.

The absurdity of the present separation of glosso-labial palsy is further shown by the circumstance that we may have such paralysis due to various apoplexies, brain-tumors, and other coarse cerebral lesions, and, to be logical, we should also isolate as a distinct disease cerebral glosso-labial paralysis.

In No. 20, *Archives de Neurologie*, is an important paper upon such an affection, by Dr. F. Raymond, in which illustrative cases are cited. The symptoms may, in case the lesion is a tumor, or other progressive alteration of brain-tissue, develop slowly, but they usually come on suddenly, because they are usually the result of clot or other apoplectic lesion, and, while they may develop alone, they are usually associated with other consentaneous palsies. Whether the manifestations come on slowly or rapidly, the cases are to be distinguished from those of medulla-disease by the absence of atrophic changes in the muscles affected, and by the preservation of the normal electrical reactions. The symptoms are stationary or progressive, as the case may be, *pari passu* with the cerebral lesion. The latter is either cortical or in the white matter. The general localization of the lesion of the white matter is in the lenticular nucleus or the external capsule, or sometimes in the internal capsule or peduncle. The foot of the ascending frontal convolution is stated to be the position in which cortical lesions cause the glosso-labial palsies.

SALT *vs.* SNOW IN THE STREETS.

THE City Councils, having solicited medical opinion as to the influence upon the public health of salt when used to melt the snow between the street-car tracks, have been supplied with opinions of decidedly diverse character.

As regards the question as to its causing zymotic diseases like diphtheria, we think that it will be generally admitted that chloride of sodium is more likely to prevent such disease than to propagate it. Indeed, any malign influence that it is capable of exerting must be exceedingly small, since the few steps that could possibly be taken by the pedestrians at the street-corners when crossing the tracks could scarcely affect the temperature of

the feet. If the inlets are kept open, so that the slush is rapidly carried away, we think that salting the track would be an advantage to the public health by aiding in keeping the streets comparatively free from snow and ice.

NOTES FROM SPECIAL CORRESPONDENTS.

NEW YORK.

THE medical colleges of this city have begun the regular course with about the same number of students and under about the same circumstances as last year. To this general statement we might add a modifying one as regards the Polyclinic and the Post-Graduate School, both of which have improved buildings and facilities for instruction over those which they possessed at the commencement of the term last fall. The Post-Graduate faculty bought and refitted a building at 226 East 20th Street, which, it is understood, is used as a college and hospital combined. The building contains a large number of compartments, so that each professor can have a room for himself in which to give instruction without the disturbances which are always likely to occur in a general lecture-hall. Dr. E. Kershner has been appointed Professor of Naval, Military, and State Hygiene.

Dr. Thomas A. McBride now shares the chair of Diseases of the Mind and Nervous System with Dr. Gray at the Polyclinic. Dr. McBride is known as a conscientious and hard worker: he will add strength to the college. The building formerly occupied by the faculty has been purchased and refitted, and now possesses nearly all the advantages which could be desired for giving post-graduate instruction. We might mention, for example, a large room with accommodations for more than thirty students to study diseases of the eye, throat, and nose, and of the ear, all the necessary apparatus being at hand. The school has a third more students than at any previous term, including professors of colleges,—among others, one from Mexico is seen, accompanied by his interpreter.

The College of Physicians and Surgeons is the recipient of the magnificent donation of five hundred thousand dollars from the hand of Mr. William H. Vanderbilt. A new building, about two hundred by three hundred feet, will be put up opposite Roosevelt Hospital. The college has an excellent faculty, and, with its new facilities, will doubtless do even more than it has been doing towards the elevation of medical education, and, indirectly, towards diminishing the sufferings of humanity.

At the last meeting of the New York County Medical Association Prof. Austin Flint read a paper on "The Parasitic Theory of Epidemic Cholera," in which he gave an excellent *résumé* of the facts and arguments for and against Koch's doctrine. Dr. Flint pleaded for a greater amount of original work in the study of the parasitic origin of diseases by American physicians, suggesting, if not prophesying, that in this field the honor of making permanent and important discoveries was to be obtained.

The health of New York at present can well be said to be good, and yet the Sanitary Bureau reports forty-two cases of typhoid fever for the week ending October 14, and fifty for that ending October 21, and of diphtheria there have been, for the same weeks, forty-five and forty-three cases respectively. The death-rate from diphtheria is pretty large, being, for the first week mentioned, twenty-nine, and for the second thirty.

The New York Obstetrical Society has re-elected Dr. William M. Polk President for another year.

The new local anæsthetic, hydrochlorate of cocaine, is being extensively tested in this city, particularly by the eye-specialists. They report favorably upon its action. Country physicians will do well, for the present at least, not to order it in pound quantities, unless they do business on the credit system.

R. C. S.

PROCEEDINGS OF SOCIETIES.

AMERICAN ACADEMY OF MEDICINE.

THE Ninth Annual Session was held at Hopkins Hall, Baltimore, October 28 and 29, 1884.

The Academy was called to order at three o'clock by the President, Dr. Benjamin Lee, of Philadelphia, who invited the Rev. J. E. Grammar, D.D., to open the session with prayer. The minutes of the last session, and the report of Council showing their action since the last meeting, were read and approved.

The following gentlemen, applicants for fellowship, having been approved by Council, were balloted for and elected: Drs. I. H. Baxter, Washington, District of Columbia; G. W. Miles, Perryville, New York; A. B. Tadlock, Knoxville, Tennessee; E. E. Barnum, Waterport, New York; C. W. Stevens, Boston; John A. Robinson, Chicago; L. L. Miner, Wilkesbarre, Pa.; H. A. Johnson, Chicago; F. S. Johnson, Chicago; J. W. Holland, Louisville; H. P. C. Wilson, Baltimore; W. W. Jaggard, Chicago; Charles Warren, Washington; J. N. Hyde, Chicago; Ira B. Reade, New York; L. S. McMurtry, Danville, Kentucky; E. O. Shakespeare, Phil-

adelphia; Douglas Morton, Louisville; M. P. Hatfield, Chicago; T. E. McArdle, Washington; S. M. Free, Dagus Mines, Pennsylvania; F. R. Graham, Chester, Pennsylvania; W. P. Watson, Jersey City, New Jersey; J. G. Young, Philadelphia; Joseph Coblenz, Baltimore; J. S. Green, Elizabeth, New Jersey; J. M. Stevenson, Pittsburg, Pa.; David Brekes, New York; E. L. Keyes, New York; E. Andrews, Chicago; E. A. Andrews, Chicago; C. Kollock, Cheraw, South Carolina; W. Murray Weidman, Reading, Pennsylvania; T. C. Stellwagen, Philadelphia; M. E. Wordin, Bridgeport, Connecticut; G. R. Morehouse, Philadelphia; E. Cowles, Somerville, Massachusetts; F. H. Davenport, Boston; E. O. Otis, Boston; T. J. Turner, Washington; T. B. Brune, Baltimore.

Drs. Bulkley, Steiner, and Bombaugh were appointed a Committee on Nomination.

The first paper of the afternoon was by Peter B. Keyser, M.D., of Philadelphia, entitled "The Relation of the Medical Colleges to Preliminary Education." This relationship was deduced from the statements made by the various colleges in their announcements, and examining those statements and the method of their execution. It appeared that but comparatively few of the ninety-one medical colleges in our country made pretence to preliminary education of any value whatever, and even among the few but a small proportion rigidly enforce their own requirements.

"The Examination of Applicants for License to Practise: A Means of Raising the Standard of Medical Education" was the title of the next paper, presented by Edward Jackson, M.D., of Philadelphia. (See page 85.)

Henry O. Marcy, M.D., of Boston, was the author of the third paper of the afternoon, having for its title "The Rôle of Bacteria in Infectious Disease." There is no subject in medicine, either in relation to its theory or practice, of greater interest, and much has been written about it,—so much, indeed, that this paper would not have been written had it not been for the assertion of "not proven" in one of a series of semi-popular lectures delivered in Boston, where the assertion was made that even in fermentation it could not be asserted to be caused by the development of a low order of vegetable organisms. This verdict was based upon the assumption that the micro-organism in any series of experiments had never been separated from the ambient organic living matter, which must be considered to have a low degree of inherent vitality, and that not until a well-washed micrococcus or bacillus had been isolated upon the point of a needle and then introduced into a sterilized nutrient solution would the real condition of the problem be fulfilled.

Since anything may be doubted, it is often well to re-examine the foundations, for science is only pure and simple truth, and never suffers by testing. The author determined to make a few experiments in the direction of the objection; for while negative truth may be as valuable as positive demonstration, the latter should not be neglected. Recognizing in the term "ambient living matter" the bioplasm of Beale, a set of experiments were conducted to determine the bioplastic power of protoplasmic matter. The blood of healthy oxen and sheep was selected, and collected under proper precautions as soon as the clot had separated; sterilized glass bulbs were filled and sealed with the flame, and others charged with sterilized culture-fluids were inoculated in varying proportions. These were kept for differing periods of time, subject to the same conditions as for the growth and testing of various bacterial organizations, and careful examination made at different dates by means of a Zeiss one-fourteenth objective giving an amplification of about one thousand diameters. In twenty bulbs change took place only in one, and in this one, upon its first opening, on the third day, there was no change.

Still further experiments were made with albumen from an egg still warm from the nest, milk aseptically milked and put up at once, and the aqueous humor from the eye. In a series of forty-one bulbs only two contained bacteria or micrococci, which were evidently accidentally introduced. It seems fair to deduce that this ambient living matter possesses no power of reproduction, which has been usually accepted, in fact.

At present no one denies that the micro-organisms exist: whether they are or are not the cause of disease is a question of importance. If the relationship of cause and effect can be demonstrated in the class of zymotic diseases, medicine will at last have a scientific foundation. Although science is pure and simple truth, we have here a very difficult problem, where probably at present generalizations are premature, but from the accumulated facts of many independent investigators he believed that such demonstration is in the near future.

To establish the action of micro-organisms they must be separated from everything else, whether living ambient matter or a chemical poison having relation to disease. This organism thus separated must, upon inoculation in the tissues of a healthy living animal of the same species, cause a reproduction of the disease.

To separate the micro-organism fully, the process of pure culture has been devised, so that in some of Dr. Sternberg's experiments less than one-quadrillionth of the original septic material remains in the eighth culture; yet a few minims of this possess all the virulence of the first, and the action is entirely different from that of a chemical poison.

With this demonstration the author passed in review the various diseases which are

proven, to a greater or less degree, to be dependent upon septic action. It may be concluded from this review that the time has passed when the critic of the germ theory of disease can content himself by captious remarks.

"The Trade-Aspect of Medicine," by Albert L. Gihon, M.D., was the next paper. (See page 116.) The object of the paper was to show the great tendency of the times to belittle the profession of medicine to a trade in medicine, to show the meanness of so doing, and to suggest a better way.

This was the last paper for the afternoon, the Academy going into executive session, when a resolution was adopted that a committee of two be appointed in each State where the Academy has Fellows, for the purpose of suggesting and furthering the appointment of independent examining boards.

THE PRESIDENT'S ADDRESS.

The evening session was given up to the President's annual address. Vice-President Gihon presided. The subject of Dr. Lee's address was, "Differentiation the Test of Civilization: The Specialist and his Education."

In selecting a topic for the annual address the President cannot go far astray if he selects some topic of an educational character, since the Academy should keep on striving until every practitioner is as well a gentleman and a scholar. He had selected the Education of the Specialist as a topic fitting the occasion and the place, since in Baltimore special practice was first recognized. In Baltimore was the first school of dentistry in which this specialty was treated as really a branch of the medical profession. In the development of any nation from barbarism towards civilization a division of labor keeps equal step with the advance, and thus increases the skill in all trades, manufactures, and business. In the learned profession the same principles have been at work, but the process has received more or less opposition,—more in this country than abroad. Thus, in England there are several recognized classes of lawyers, each with special qualifications. The same is true here, but they have all the same title.

The science of medicine is expansive, while law and theology are fixed, and yet the opposition has been stronger to separation in medicine than in the other professions. The arguments against the practice of specialties may be classed under three heads: 1st. The multiplication of specialties has a narrowing effect upon the doctor practising the specialty. 2d. It degrades the profession. 3d. It is not best for the patient.

On the other side it is claimed that specialism is nothing new, strange, or foreign. Medicine itself is a differentiation, for in times past the priest and physician were one. Then there are surgeons, physicians, obstetricians, and alienists. Why not carry the division further? The day of the cyclopædist is over, and men are not able to be proficient in the whole circle of medical science. Why should they not concentrate upon a portion? The more specialized the animal, the more important it is; so in social life, the more complex it becomes, there is the greater need for specialists. Here, as elsewhere, differentiation is a test of civilization. The defence calls witnesses and asks if there have not been important contributions to medical knowledge from the studies of specialists. So are the arguments, and in whatever way we may look at it two facts seem patent,—the specialist has come, and he has come to stay. And whether we think of him as the product of a degenerated race or the flower of the profession, we ought to make the best of him. What shall he be, a physician and something more, or something less than a physician? He should have, if possible, even a better preliminary training than the general practitioner; the self-consciousness of a dwarfing due to the special line of study is belittling, and his preliminary education should be broad. As to his medical education, he has use for all of the old seven sets of subjects, except, perhaps, obstetrics, for this is a special study; and, as he is apt to see disease in its more chronic form, the residency in a general hospital where acute forms of disease can be seen would be of use. Then comes the special training, whether at Alma Mater or in a polyclinic. With such a training a specialist will not threaten the profession.

At the conclusion of Dr. Lee's address the Fellows adjourned to the Athenæum Club, where they had their annual collation, having a most enjoyable time.

SECOND DAY'S SESSION.

The Council recommended the election of Drs. George M. Sternberg, U.S.A., and Oliver Wendell Holmes, of Boston, as honorary members, and the following gentlemen for fellowship: Drs. R. J. Levis, of Philadelphia; J. W. Kerr, of York, Pennsylvania; Alexander Hadden, of New York; and J. D. Kelley, of Utica, New York; making forty-five in all.

They also presented a series of amendments to the constitution and by-laws for the purpose of making another class of members,—Associates, who shall consist of those who have attained distinction in medicine and the collateral sciences and do not possess the degree in arts, the qualification of a Fellow. These lie over under the rules until the next session. The following resolution was adopted:

"*Resolved*, That the American Academy of Medicine recognizes in the recent munificent gift of Mr. W. H. Vanderbilt to the College of Physicians and Surgeons of New York a most important and valuable service to the science of medicine in America.

"That in this spirit the Academy tenders to Mr. Vanderbilt its obligations, with the assurance that in no better way could the higher education of our profession and the benefit of humanity be promoted."

The nominating committee presented the following report, which was accepted and the gentlemen elected:

President.—Albert L. Gihon, M.D., U. S. Navy.

Vice-Presidents.—R. Stansbury Sutton, M.D., Pittsburg; James A. Stewart, M.D., Baltimore; William Elmer, M.D., Bridgeton, New Jersey; J. Cheston Morris, M.D., Philadelphia.

Secretary and Treasurer.—R. J. Dunglison, M.D., Philadelphia.

Assistant Secretary.—Charles McIntire, Jr., M.D., Easton, Pennsylvania.

The first paper of the morning was by A. D. Rockwell, M.D., of New York, on "The Induction Coil: its Varieties, and the Differential Indications for their Use."

By means of diagrams the two kinds of induction coil, the separate and continuous coils, were explained, and a preference was expressed for the latter form, from the ten currents, of which the author had separated three capable of performing the work of the whole ten.

First.—The current obtained from the primary coil of large quantity and small tension, having little contractile power upon muscles in health; useful in head-neuralgia and asthenopia.

Second.—The combination of the primary coil with the first and second induction coil, giving a current which has the maximum power to contract muscles, each additional coil weakening it in this direction. It is harsh and unpleasant, and of use when a profound impression is desired.

Third.—A combination of the primary in connection with all three induction coils. Very important tonic and sedative in character; to be used in general faradization.

"Some Comparative Results of Treatment of Chronic Articular Osteitis of the Hips," by V. P. Gibney, M.D., of New York, was read by title and referred to Council.

C. C. Bombaugh, M.D., of Baltimore, read the next paper, entitled "The Place of the Physician in Literature." This paper, by careful quotations concerning doctors from the writings of all time, was a means of "seeing oursels as ithers see us," and, by analyzing the criticism and satire, showed clearly that there was much foundation for the sport made of the profession, while, unfortunately, the profession were not always willing to profit by the portrait. Looking about us, there seems to be ample opportunity for other Molières, unless the profession improve and are wise to learn.

"Observations in One Hundred and Thirty-seven Abdominal Sections" was the title of a paper by R. Stansbury Sutton, M.D., of Pittsburg.

The cases upon which these observations were founded were operated on by various operators in America and Europe, and comprised the various forms of abdominal section.

McDowell's operation, as a rule, is performed upon patients of the poorer class, in this country, not until late, when the health is broken down; in Scotland, England, and Germany earlier, and in a special hospital; in Austria not so early, and in the general hospital, where the successes are not so great. The author favors the English plan. An ovariotomy done early may be considered one of the easiest of surgical operations; but a neglected case is a very different affair. After the completion of the operation it is most important to leave the peritoneal cavity perfectly dry. As a rule, the younger subjects do best, but older people bear the operation well. Climatic influences seem to have but little effect upon the success of the operation. Cleanliness to the last detail must be insisted upon. The prevention of the loss of blood is of the greatest importance. Drainage in intra-abdominal operations should only be resorted to when from any cause fluid might be poured into the cavity. Abdominal operations are growing in frequency every year, and after excluding pregnancy, renal and heart disease, there is a tendency not to attempt a diagnosis of the character of the tumor until after section.

The author strongly recommends the selection of cases for operating, refusing those who have been tapped so often that success is almost impossible, for the purpose of putting a stop to the operation of tapping by the family practitioner, and because a fatal operation is apt to deter others who would probably have a favorable result.

At the conclusion of Dr. Sutton's paper the Academy took a recess to visit the laboratories of Johns Hopkins University.

Upon reconvening, after a discussion upon Dr. Sutton's paper, L. Duncan Bulkley, M.D., of New York, read a paper on "Specialties and their Relation to the Medical Profession," in which the author concluded that the science and art of medicine was too vast for one mind; so there must be divisions of study. But the foundation should be one. A man should rather grow into special practice than be pruned into shape for it.

"Physiology in its More Public Relations," by Nathan Allan, M.D., of Lowell, Massachusetts, was read by title, and referred to Council. Telegrams were received from Drs. Knapp and Chrystie, of New York, expressing their regret at their inability to be present with their papers.

The report of the Committee on Laws regulating the Practice of Medicine was read in part.

Dr. Lee introduced the President-elect, Dr. Gihon, who appointed Drs. L. Duncan Bulkley and E. H. M. Sell, of New York, as additional members of Council.

Votes of thanks were given to the retiring President, Dr. Lee, and the authorities of Johns Hopkins University, and the Academy adjourned.

After adjournment the Fellows visited the Johns Hopkins Hospital, under the guidance of Dr. J. S. Billings.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held October 16, 1884, FORDYCE BARKER, M.D., LL.D., President, in the chair.

The President invited Dr. JOHN SCOTT, of San Francisco, to take a seat on the platform.

Dr. H. MARION SIMS presented to the Academy a BRONZE BUST OF DR. J. MARION SIMS, it being a copy of a marble bust by the eminent Parisian sculptor, Du Bois.

Dr. WILLIAM H. DRAPER then read

A MEMOIR OF THE LATE WILLARD PARKER, M.D., LL.D.

The scientific paper of the evening was read by AMBROSE L. RANNEY, M.D., and was entitled

THE THERAPEUTICAL EFFECTS OF THE INTERNAL ADMINISTRATION OF HOT WATER IN THE TREATMENT OF NERVOUS DISEASES.

The author spoke of a mutual dependence existing between disorders of the thoracic, abdominal, and pelvic viscera and some forms of functional disturbance of the nervous system. This remark was prefatory of what should follow.

Hot water is largely used among the laity at the present time as a medicinal agent, and this use had been suggested principally by word of mouth, and not by published matter. The treatment seems first to have been employed by Dr. Salisbury in 1858.

After directing attention to the modes of action of heat, Dr. Ranney said the benefits which resulted from the internal use of hot water must be due, in part at least, to heat. Some of its effects were manifested almost immediately in organs not connected with the digestive apparatus.

The following rules were laid down for the administration of hot water. 1. It should be taken in doses of from one goblet to one and a half. 2. It must be drunk hot, from 110° to 150° Fahr. If necessary, fifteen minutes or more might be consumed in sipping it. 3. It should be taken an hour and a half before each meal, and also at bedtime. The quantity taken daily should be modified according to the effects produced. 4. The temperature of the water should be increased as fast as the patient could bear it. Below 110° it acted as an emetic. 5. The administration should be continued for at least six months to get the full effects. It would be some weeks, as a rule, before any beneficial effects became markedly apparent. 6. The dose should be determined largely by the specific gravity and general character of the urine. If it fell as low as 1.010 the dose should be reduced to one-half a pint; if it reached 1.030 it should be gradually increased to a pint, provided there was not profuse sweating, with diminished quantity of urine. 7. The use of cold fluids should be absolutely prohibited. 8. A restricted diet was often necessary to the full effects of the treatment in some forms of nervous derangements. With some patients he forbade sweets, fats, and pastry; in others he allowed only a lean-meat diet.

The effects of this treatment were manifest in increased activity of the skin, warmth of the extremities, the circulation became more uniform, and it was believed that the viscera became disengorged; the quantity of the urine was increased; the accessory organs of digestion, the liver and pancreas, were stimulated; the fæces, which at first were dark, became soft and yellow, taking on more the appearance of the fæces of the infant. He had known the treatment to check hæmorrhoidal bleeding and chronic diarrhœa. He believed certain cases of locomotor ataxia had been benefited, but other forms of treatment were continued at the same time. Some cases of diabetes had rebelled against every other form of treatment, including that of diet, but when hot water was added the patients began almost immediately to improve, and in a short time were apparently cured. It had cured three cases of gastralgia with extreme paroxysms. Neurasthenic patients were almost invariably benefited,—those presenting symptoms of cerebral hyperæmia and anæmia, etc.

Dr. Ranney thought the neurotic theory of the action of the hot water the most plausible, and then spoke of the intimate relationship between the several centres of the vaso-motor nerves to one another and to the cerebro-spinal system, both as to connection and reaction upon one another. Did not the hot water produce a direct effect upon the solar plexus, which lay just behind the stomach, and by reflex action upon the other system of nerves?

Dr. Ranney believed the chief benefit derived from a visit to the hot-water springs was due to the agency of heat, to a restricted diet, and to enforced physical and mental rest.

DISCUSSION.

Dr. E. C. SEGUIN had not had much experience in the use of hot water, and had never employed it in purely organic affections of the nervous system. He thought there were

several points in the paper which were open to some question. He thought, for instance, that the water did not reach the stomach in a sufficiently hot state to act in the manner suggested by the author. While passing to the stomach it lost some of its heat, just as ice-water imparted some of its cold: there was a tendency to equalization of the temperature of the fluid and the food-passages. Again, many of the disorders spoken of as affections of the nervous system were due to, or at least associated with, disorders of the digestive system, with mal-assimilation, and in these cases the restricted diet of itself would often prove very beneficial. He asked the question if it was not possible that the benefit was due to the water as a fluid, and not to its heat-properties. Many patients had a lack of desire for water, and it had been found that if they could be induced to take more than what their appetites called for they would receive benefit. The theory advanced regarding the action of the agent might have some foundation, but he thought a good share of the benefit produced was to be attributed to the water itself, and but little would be left to attribute to the action of heat. Dr. Seguin then spoke a word in favor of cold water, ice-cream, etc. They did not reach the stomach ice-cold.

Dr. R. W. AMIDON had for some time used hot water in the treatment of nervous phenomena connected with dyspepsia or the gouty and rheumatic diatheses. He agreed with the last speaker, that the action of the hot water as a derivative or counter-irritant was extremely doubtful. He did not believe that when it reached the stomach it was sufficiently hot to produce a counter-irritant effect. He understood the author to say that the beneficial effects of the hot water were obtained only after six months, but Dr. Amidon's experience taught him that counter-irritants acted much sooner than that. He believed the hot water acted more as a diluent; that it increased destructive metamorphosis and the powers of assimilation.

Dr. L. PUTZEL thought the theory concerning the action of hot water taken into the stomach, as advanced by the author of the paper, proved too much, for he had said that the agent had proved of benefit both in cases of cerebral hyperæmia and cerebral anæmia, and Dr. Putzel did not think it could act beneficially in opposite conditions. He would lay some stress upon the point made by Dr. Amidon, that an agent which acts by its irritant effects should produce its results quickly. He should suppose that the best results from the use of hot water would be obtained in the commencement of the treatment, as afterwards the stomach would become habituated to the irritation.

Dr. W. B. BIRDSALL believed that there was a good deal of efficacy in hot water, as well also in cold water, when used as therapeutical agents. He was not prepared to deny the influence which it had been stated heat played in this mode of treatment. But what he had been most anxious to hear was statistics of a clear character which would enable us to judge of the effects of hot water, particularly in the class of cases which were strictly disorders of the nervous system, as locomotor ataxia. But, unfortunately, the cases related had been submitted to a combination of treatment, and not to that by hot water alone, and we were therefore unable to tell what part had been played by this agent in the production of beneficial results. In the cases of functional disturbance of the nervous system it would be difficult to say how much of the good result was to be attributed to the element of heat and how much to the diluent properties of the agent. He thought the hot water might begin to produce its effects as an agent of heat the moment it came in contact with the mucous membrane in its passage down to the stomach. His impression was that it was not the influence of the heat upon the vaso-motor system alone which caused the results. It might also have produced some influence upon the other system of nerves.

Dr. C. L. DANA had used hot water in cases of nervous disorder associated with gastric disturbances, particularly in hysterical women, but he had not been favorably impressed with its efficacy. The want of favorable results, however, might possibly have been due to lack of carrying out the treatment so persistently as the author recommended. He believed that the paper would result in benefit in suggesting a mode of treatment for a class which usually resisted almost all kinds of treatment, and, as Dr. Wilks had years ago pointed out, those agents which were not directed immediately to the nervous system were more likely to prove efficacious in the treatment of this class of disorders.

Dr. J. L. CORNING had obtained good results from the use of hot water in cases of so-called neurasthenia with concomitant gastric disorders. He had attributed the good effect to the influence produced upon the mucous membrane of the stomach by the hot water. He had obtained good results in from six weeks to two months.

Dr. JOHN SCOTT, of San Francisco, had employed hot water in checking emesis, especially after the administration of ether. He had also given water in the form of a milk diet with great benefit.

Dr. RANNEY, in closing the discussion, said that any one who would take hot water as he had recommended would be convinced after drinking it that it reached the stomach in more than a warm state. Hot water could not lose much of its heat before it reached the stomach. It had been suggested by some of the speakers that the beneficial effects produced by the hot water were due to its diluent qualities, but he had obtained results with

*

four goblets of hot water a day which could not have been obtained by as many gallons of water in its ordinary state. He had been misunderstood to say that the effects were produced only after the lapse of six months. What he did say was that in some cases it took from five to six weeks to get marked effects, and in some six months to produce the full effects. The theory which he had suggested concerning the action of the agent seemed to have been the chief basis of the discussion and adverse criticism. He had advanced the theory simply as being to him the most plausible, but it might be entirely incorrect, yet the facts as to the result of treatment by the swallowing of hot water existed. As to Dr. Putzel's criticism, that benefit could not be produced in opposite conditions in both cerebral hyperæmia and cerebral anæmia, he would say the agent had a tendency to restore the parts to their normal condition, and in so doing would tend to relieve any abnormal condition which might exist in the brain. One man who drank whiskey would become bloated and fat, while another, taking the same agent, would lose flesh and become thin. It had been doubted whether his cases proved anything, as different agents were employed in the treatment at the same time. But the other measures had failed to produce any benefit until combined with the use of hot water. It followed, therefore, either that the hot water alone had produced beneficial result, or that hot water combined with other remedies had done so.

Dr. T. H. BURCHARD asked Dr. Ranney whether he had observed any permanent disturbance of the digestive system produced by the hot water when used for some time, and also whether he had observed that it caused a tendency to internal hemorrhages. He had seen many patients at Saratoga Springs, who had been treated by this method, and, after five or six months, had experienced disturbance of digestion, had lost flesh, and become greatly reduced in health; and others had shown a tendency to gastric and intestinal hemorrhage.

Dr. RANNEY replied that he had never known intestinal hemorrhage to occur in a patient to whom he had administered hot water, and he had treated a great many patients in this manner. Nor had he known it to produce permanent disorder of the digestive powers. He had known patients to rapidly lose weight, but it was due to the restricted diet which had been purposely recommended, and they would quickly regain their weight on returning to a general diet.

A NEW ANÆSTHETIC.

Dr. C. R. AGNEW made some remarks upon hydrochlorate of cocaine as an anæsthetic when applied to the conjunctiva. Since attention had been called to the subject by a letter published in the *New York Medical Record*, October 11, he had employed the agent in a number of cases in which he had performed operations upon the eye, and both he and the observers had been greatly satisfied and astonished with the beauty of its action. He felt that nothing of greater value had been given to surgery since the discovery of ether and chloroform. He distinctly disclaimed any priority in its use in this city. The action of the agent was demonstrated upon two gentlemen present at the meeting. It had not been positively determined whether the agent was capable of producing local anæsthesia in wounds of the skin.

Dr. BURCHARD said it had produced anæsthesia in the finger, the seat of a felon, so that he had been enabled to open the felon without pain to the patient.

Dr. BIRDSALL had been in the habit, the past two years, of employing erythroxylon coca to produce a benumbing effect upon the mucous membrane of the air-passages.

The PRESIDENT referred to the effects of the fluid extract in clearing the voice.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held October 22, 1884, GEORGE F. SHRADY, M.D., President, in the chair.

GENERAL CARCINOMA.

Dr. JOHN A. WYETH presented a specimen with the following history. A German, 38 years of age, was admitted to the Mount Sinai Hospital, September 10. In May last he noticed a tumor to the left of the umbilicus, which grew until, by its size and position, it gave him much inconvenience. On admission, the tumor involved the umbilical, left inguinal, and lumbar regions, extending downward to the symphysis pubis. The patient had lost eighty pounds in weight during the last four months. Pressure over the tumor, under the liver, over the left kidney, and also over the thorax on the left side, gave rise to pain. There was some bulging at the upper part of the left side of the chest, the outline of the clavicle being entirely obliterated. The left axillary and supra-clavicular glands were enlarged. There was marked dulness, diminished voice and breathing; crepitant, subcrepitant, and sonorous râles at the left apex anteriorly; also marked laryngitis, loss of voice, and spasmodic cough. The patient suffered constantly from pain. On the 16th of September the patient felt great pain in the left leg and thigh, the limb became cold and mottled in color, the foot anæsthetic; there was no pulsation in the femoral artery. Swelling of the limb increased, accompanied with pain in the course of the femoral artery, and several blebs developed near the ankle. The patient died on the 15th of October, of signs of pulmonary œdema. At the autopsy a large carcinoma was

found occupying the left inguinal and lumbar regions, covered by the mesentery and attached to the vertebral column, also to the descending colon and left kidney. Hydronephrosis had resulted from compression of the ureter. The tumor seemed to arise from the lower dorsal and lumbar glands, and surrounded the aorta and vena cava. The left external iliac artery was flattened, and there was thrombosis of the vein extending down into the femoral. The anterior mediastinum was occupied by a new growth attached to the sternum, extending backward, surrounding the trachea and great vessels of the neck. The apex of the left lung was pushed to the left by the tumor. The liver and bladder were the seat of broken-down white foci.

An interesting point in the history of the case was the fact that in April last Dr. Gerster removed the left testicle, which he presented to the Society as a specimen of tubercle testis.

INHALATION OF A BLOW-GUN DART—SPONTANEOUS EXPULSION AFTER TRACHEOTOMY.

Dr. WYETH presented a blow-gun dart, consisting of a pin with a cotton wad attached, which had been swallowed by a boy 10 years of age on the 7th of September. Violent cough followed immediately after the dart was inspired, and the mother thought the boy would choke to death, but the symptoms of suffocation disappeared shortly, not to return again until the foreign body was coughed up. The patient was carefully examined by the family physician, who concluded the dart had reached the right bronchus, and when he was brought to New York, Dr. Wyeth, Dr. Elsberg, and Dr. Leaming were of the opinion that the foreign body was in the right bronchus, and consequently, on the 11th of September, Dr. Wyeth performed tracheotomy and searched for the body. He first introduced the little finger, and afterwards used a pair of forceps, opening them a quarter of an inch and pushing them forward a quarter of an inch in different directions, closing them, but failed to touch what seemed to be the object sought for. A piece of ordinary surgeon's wire, doubled, was also passed, but in vain. The wound was kept open until the 24th of September, the patient doing well, when another consultation was held with Drs. A. Jacobi, E. G. Janeway, and J. H. Ripley. Dr. Ripley thought the dart had become loosened, was coughed part of the way up, and fell again with the next inspiration into the left bronchus. The next day Dr. Wyeth enlarged the tracheal wound to insert a silver tube. The wound being open, he introduced the finger into the left bronchus to see if it might not be possible the dart had changed its position. This procedure, which was repeated twice, gave rise each time to violent expiratory efforts, which finally resulted in throwing the pin, with the wad attached, out of the mouth. The patient had not been fully under the influence of the anæsthetic; hence the irritative effects produced by inserting the finger into the bronchus. Dr. Wyeth was having an instrument made by which he hoped to be able, in cases of this character, to remove the foreign body by suction-force through a tube introduced into the trachea.

The PRESIDENT thought that, as a rule, foreign bodies were expelled from the air-passages by a violent expiratory effort, and it might be well, in cases in which the bodies were of a round form, to wait for them to be raised spontaneously. In cases like the one related by Dr. Wyeth, in which it was evident the point of a sharp body was upward, it would be safer to explore the trachea and bronchi. He once removed a spiral spring of a clothes-pin from the top of the larynx in a boy about five years of age, who was about to suffocate, using his finger as an instrument of extraction.

Dr. H. C. COE referred to the case of a young man who suffered from symptoms of consumption after swallowing a head of timothy. The foreign body was coughed up after about a year, and the patient completely recovered.

Dr. J. LEWIS SMITH referred to the case of a child which had fibroid pneumonia the result of inhaling a piece of hickory-nut-shell. Recovery took place after spontaneous removal of the nut-shell, at the end of three months from the time of its inhalation.

Dr. FURMAN knew a patient to recover from lung-symptoms after coughing up a piece of tooth which had been inhaled while he was under the influence of an anæsthetic.

TUMOR OF THE BREAST.

Dr. W. P. NORTHRUP presented a tumor of the breast which Dr. C. C. Lee had removed, at the Foundling Asylum, from a woman 45 years of age, the mother of ten children. The tumor began to develop just before the birth of her last child, and when removed, seven weeks after the birth of the child, was as large as an orange. The case had been seen by five or six eminent surgeons of the city, all of whom pronounced it one of malignant disease and recommended immediate removal of the breast. The tumor was nodular and hard to the touch; the nipple was retracted; there were a few enlarged glands in the axilla. When Dr. Lee cut into the tumor there spurted forth fetid matter to some distance, so tense were the cyst-walls, and all present thought he had cut into an abscess. He then removed the ragged walls, the tissue on the posterior wall being very hard; the anterior wall was quite thin. He did not remove the axillary glands. The prognosis was considered doubtful. The microscopical examination left some doubt as to the exact nature of the tumor, but Dr. Northrup and Dr. Delafield were inclined to think that

originally it was an adenoma, an abscess developing in its centre later. There were numerous giant cells in the specimen. The wound healed almost entirely by first intention. The axillary glands had diminished in size since the operation.

Dr. WYETH was disposed to regard the giant cells as an indication of sarcoma or of tubercle.

The PRESIDENT said the description of the case, as given by Dr. Northrup, corresponded almost exactly to that of a case in which he operated two years ago, removing a tumor from the breast and enlarged glands from the axilla. The cyst-walls in his case were also very tense. At that time he thought the prognosis good, but malignant disease had developed in the glands of the neck, and two operations were subsequently performed, and now the patient was dying of gradual suffocation and asthenia. He thought it would have been proper to remove the enlarged glands in the axilla in Dr. Northrup's case. He should regard the prognosis as very unfavorable.

ULCERATIVE ENDOCARDITIS.

Dr. J. LEWIS SMITH related the history of a case of ulcerative endocarditis, as follows: The patient was a girl 5 years of age, who two years before had had double lobar pneumonia, and two months before had had pertussis, but her health immediately before the fatal disease was good. She began to be sick on the 16th of August, with fever and loss of appetite. Pneumonia was suspected, but definite signs did not exist. Dr. Smith saw the patient nine days later, at which time he was unable to make a clear diagnosis. There were no physical signs of pneumonia; the heart-sounds and the urine were normal; the temperature in the groin was 104.5°, the pulse 150, the tongue dry and furred, respiration a little accelerated. That night, the 25th of September, the patient slept well and had two stools of the natural appearance; the pulse 160, the temperature in the groin 102.4°. On the evening of the 26th the patient had a copious evacuation of very dark blood. On the 27th the pulse 160; there had been one normal evacuation from the bowel. On this day the patient began to vomit, and continued to vomit nearly every day until death, the temperature varying morning and night from 101° to 105°. On the 4th of October the patient vomited blood. She died on the 5th, in a state of great prostration. There was some extravasation of blood under the skin on the last day of life. At the autopsy the mucous membrane of the stomach and intestines was mottled with extravasation of blood. There were some points of extravasated blood in the lungs and liver. In the anterior, and more or less in the posterior, lobes of the brain were extravasations, in some places filling the sulci. On the mitral valve was a polypus a quarter of an inch in length, and two other polypi were found on the heart-walls, covered with fibrin. The entire endocardium seemed to be much thickened. The polypi contained numberless micrococci.

Dr. H. C. COE referred to two cases of tumor of the abdomen, one having been diagnosticated as an ovarian tumor and the other as a cyst of the kidney. Examination of the blood showed that the patients were suffering from leucocythæmia, and they were thus saved the perils of an unnecessary abdominal operation.

PHILADELPHIA CLINICAL SOCIETY.

STATED MEETING, SEPTEMBER 26, 1884.

DR. CLARA MARSHALL read a "Report of Two Cases of Imperforate Anus, with Recto-Vaginal Fistulæ, in the Adult." The paper was reserved for publication by the reader.

A case of *Atresia Vaginæ with Retention of Menses* was reported by Dr. E. E. MONTGOMERY. Miss F., æt. 44, single, of healthy parentage, was brought to my office July 5, 1884, by Dr. Sibbald, of this State, with the following history. She commenced menstruating at sixteen, and continued without disturbance until her thirtieth year. Two years previously she had fallen upon a curb-stone, receiving quite serious spinal injury, which lasted a year, when she fully recovered. The menstrual periods, which were always regular, lasting from three to four days, normal in quantity and color, at thirty became painful. Since then the pain has been constant and increasing with each period. The discharge now lasts from seven to ten days, is of a dark bloody nature and offensive odor. During the menstrual intervals there is a continuous discharge of "corruption," as she calls it, necessitating the constant wearing of a napkin and producing excoriation. All of these symptoms have been increasing during the past eight years, and she has been compelled to discontinue work a week or more at a time. She complains of a sensation of weight or pressure in the pelvis, attended with severe pain during defecation. There is no pain during micturition. Her nervous system has become much affected.

Upon examination, the vagina was found relaxed and the external parts red and bathed with secretion. The vagina was about two inches long, ending above in a lateral cicatrix. No uterus could be felt. Upon withdrawal, the finger was found bathed with a dark, thick, highly offensive discharge. The use of a Sims speculum disclosed a cicatricial line running from side to side across the fundus of the sulcus, just posterior to which the membrane looked thinner. Slight press-

ure against this with a sound perforated it, and was followed by a profuse discharge of broken-down blood and pus. A pair of Ellinger's dilators was then introduced and spread to their full extent; over four ounces of the fluid flowed out. The cavity was then washed out with a carbolized solution. In this cavity, above the cicatrix, the uterus was found retroverted and firmly fixed, forming the roof. The cavity was dressed with carbolized glycerin on cotton. Subsequent treatment was conducted by Dr. Sibbald. He informs me that there has been no difficulty since, and that she now feels perfectly well.

Dr. W. H. PARISH: That the treatment adapted in this case was proper, the results showed, though it was not in accordance with the treatment directed by the text-books. We are there told to puncture the cavity with a trocar, and draw off the confined liquid drop by drop. This is undoubtedly wrong, and its disadvantages have been demonstrated in my own practice. The crucial incision is undoubtedly best.

Dr. COLLINS related the details of a case treated in the manner of the text-books by exploratory needle, trocar, and drop-by-drop drainage. The cartilaginous membrane acting as septum was one and a half inches from the vulva, and probably congenital. A crucial incision was made after drainage, and the corners cut off, and no further trouble was experienced by the patient.

Dr. MONTGOMERY, in closing the discussion, said, "As Dr. Parish has said, the free incision is best, though it was precipitated in the case related by an opening occurring during examination. The danger of septicæmia is certainly increased by a small opening. A particular point of interest in this case was the lateness in life and the time that elapsed between the injury and the retention."

G. BETTON MASSEY, M.D.,
Reporting Secretary.

REVIEWS AND BOOK NOTICES.

OSTEOTOMY AND OSTEOCLASIS FOR DEFORMITIES OF THE LOWER EXTREMITIES. By CHARLES T. POORE, M.D., Surgeon to St. Mary's Free Hospital for Children, New York; Member of the New York Surgical Society, etc. D. Appleton & Co., New York, 1884, pp. 187.

Dr. Poore has written a valuable history of osteotomy and osteoclasis, the methods of their performance and the diseases for which they are required. He has carefully, though by no means arbitrarily, determined the form of operation best adapted to each variety of deformity, and has succeeded in conveying these distinctions to the reader.

Rickets, the cause of most of these deformities, the author does not regard as an inherited vice of constitution, but as a general disease of the individual produced by malnutrition; and he claims that "bad air, improper food, and scanty clothing may make the healthiest child the victim of this disease."

He has found most of these deformities produced at the periods of rapid growth, before the seventh or between the twelfth and twentieth years, when the production of cartilage is more rapid than that of the earthy salts. The actual distortion he regards as entirely due to the weight of the body, and not to muscular contraction.

The author's views on one of the great questions of the day (if it can still be regarded as a question) are worth quoting:

"It has only been since the methods of treatment of wounds advocated by Mr. Lister that surgeons have felt justified in operating upon tissues with which their predecessors considered it too hazardous to interfere. Although much of the strict technique of Listerism has been abandoned, yet its fundamental principles have stood the test of time, —viz., cleanliness, drainage, and rest.

"In regard to the use of Listerism, I am clearly of the opinion that it affords no additional safety, and I have long since abandoned its use. I do not place my instruments in any antiseptic solution before using, and I do not regard it as essential to keep the wound damp with carbolized water."

He quotes Macewen, however, as dressing his wounds with iodoform and washing them out with carbolic acid.

After the above statement, one naturally turns to the table of results. We find that he has performed 91 osteotomies, of which 15, or over 16 per cent., suppurated, while of 1510 osteotomies collected from all sources, 109, or about 7 per cent., suppurated.

Dr. Poore prefers the osteotome to either Adams's saw or Shrady's modification, as it is less difficult to work, takes less time, and lacerates the soft tissues less.

After operation the limbs are at once straightened and put in plaster of Paris, to remain until bony union has taken place. He expects primary union of the wound, but observes it through a fenestra, as he does not rely upon the thermometer to indicate the presence of pus.

He considers it very unwise to correct deformities or to attempt to regain motion after suppurative coxalgia, and pronounces it very dangerous under any circumstances.

He found that out of 167 sections for coxalgia many suppurated, and 17 died. He prefers the long splint to permanent plaster dressings in sections about the hip.

The author treats his cases of genu valgum with splints or braces, if they reach him before hardening of the bone has occurred. This he determines by grasping the tibia

firmly at each extremity and trying to "spring" it. If it bends under these circumstances, he uses braces; if no improvement follows in a few months, he operates.

The mechanical treatment is not, however, very successful. He quotes one hospital service, where the patients are particularly well cared for, with only 23 per cent. of cures.

Ogston's operation seems to the author to be dangerous on theoretical grounds. Reeve's is difficult to perform, and it is occasionally impossible to slide the condyle up. Nor does he regard favorably Barwell's method of dividing femur, tibia, and fibula.

The author regards division just above the epiphysis as applicable to all cases of knock-knee dependent upon femoral changes. He gives a full description of all the operations, but considers that "Macewen's operation has superseded all others. It is easier to perform, is applicable to all cases, it is distant from the joint and its ligaments, and is near, if not at, the point of abnormal deviation."

He has modified Macewen's operation by omitting Listerism, flexing the leg instead of extending it, and differs in the method of treating the wound.

Of 622 cases of Macewen's operation there had been but three fatal cases, and in but one was the death due to the operation.

For genu varum the author advises osteotomy at the point of greatest curvature.

Dr. Poore fully reviews the history of osteotomy for angular anchylosis at the knee-joint from John Rhea Barton to the present time. He regards Buck's method, that of excising the entire joint by a cuneiform osteotomy, leaving a small portion of bone to protect the vessels, as the safest and best operation.

We have seen it necessary, when this operation has been performed, not only to excise the entire diameter of the bone, but to remove several further sections from either the femur or tibia, to straighten the limb, owing to the adapted shortening of the tissues posterior to the joint. This made the limb so much shorter as to convince us of the superiority of a section above, in Macewen's line.

In his cuneiform osteotomies for angular deformities of the tibia, the author makes a primary counter-opening posteriorly, keeping carbolized horse-hair in it for at least two days. Osteoclasis is now but seldom used except to correct deformities after fracture. In fifty-three refractures of the femur and twenty-four of the leg the results are reported as perfect.

The author prefers Rizzoli's osteoclast. With this instrument, he states, the point of fracture is entirely under the control of the surgeon, and is sharply transverse.

The author has performed seventy-four linear and seventeen cuneiform osteotomies. The deformity was corrected in all exeept two. Suppuration occurred in eight of the linear and seven of the cuneiform. There were no deaths directly from the operation.

He has performed osteoclasis thirty-four times, with perfect recovery in all.

He has collected 1510 cases of osteotomy: 1448 were linear and 62 cuneiform. Of the former 15 died, in 92 suppuration occurred, and in 17 there was some necrosis. Of the cuneiform osteotomies, 17 suppurated and 5 died.

The book is a most welcome and valuable contribution to surgery. J. M. B.

A Manual of Diseases of the Throat and Nares. By Morell Mackenzie, M.D. Lond. Vol. II.—Diseases of the Œsophagus, Nose, and Naso-Pharynx. 8vo, pp. 400, 93 Illustrations. American Edition. William Wood & Co., New York, 1884.

The book before us is the long-expected second volume of Dr. Mackenzie's comprehensive work on diseases of the throat and nose, which was to follow closely upon the appearance of the first volume, but was delayed until now by peculiar circumstances.

As the English edition has already received notice in these pages, we need not again refer to the systematic arrangement and lucid explanations which give this work special value for reference. We may observe, however, that the views expressed in regard to the pathology and treatment of nasal diseases are in some instances different from those held by most of the leading laryngologists of America, and it will be found that some of the later, but not unimportant, achievements attained by Americans are not mentioned, as, for instance, the treatment of hay-fever by the galvano-cautery, and the existence of cystic polypi in the nares, as reported by Lefferts and Seiler. We can, however, fully endorse the author when, in speaking of the treatment of nasal obstruction, he says, "'To cut through everything soft, to saw through everything hard, and to tie everything that bleeds,'—the spirit of this simple instruction in surgery has, I fear, in recent years sometimes influenced the young practitioner, and the nasal passages have occasionally been 'cleared' with a zeal and energy worthy of the industrious backwoodsman." More interesting than useful perhaps for the general practitioner are the chapters on rhinoliths, maggots, and insects in the nares, which accidents are so rarely met with, and then only in certain parts of the world, that their description has only been added for the sake of completeness. One of the great charms of the volume is the elegant and easy language in which it is clothed, making its perusal a pleasure rather than a labor. The wood-cuts illustrating the text are well executed, and add greatly to the appearance as well as to the value of the book,

and the general appearance is such as to do credit to the well-known publishing firm.

C. S.

INDEX-CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, U.S.A. Authors and Subjects. Vol. V., Flaccus–Hearth. Government Printing-Office, Washington, 1884.

In announcing the fifth volume of the Index-Catalogue we can only express our congratulations to Dr. Billings upon the continued progress of this great work, which is an honor to America and American physicians. This issue contains more than 15,000 author-titles, representing 5755 volumes and 12,896 pamphlets; it also includes 8069 subject-titles of separate books and pamphlets and 34,027 titles of articles in periodicals. The greatest number of references appear appropriately under the Head and the Heart, the latter comprising no less than a hundred pages.

Such a list of references is very discouraging to authorship, and is well calculated to sprinkle thorns in the path of the painstaking essayist.

MEDICAL RHYMES, ETC. Selected and Compiled from a Variety of Sources. By HUGO ERICHSEN, M.D. With an Introduction by Prof. WILLIS P. KING, M.D. Illustrated. J. H. Chambers & Co., St. Louis. Cloth, 8vo, pp. 220.

In this collection of medical rhymes, wise and otherwise, there are some old friends and many recent aspirants for favor. The "Lines to a Skeleton" and the "Address to a Mummy," with Dr. Holmes's "Stethoscope Song" and Weir Mitchell's "Lines to a Deserted Study," are found in association with medical ditties, humorous or pathetic, and of varying interest and value. It is a book that will afford a pleasant half-hour to the traditional overworked doctor who comes home wearied with the drudgery of his daily round of practice.

A SHORT TEXT-BOOK OF INORGANIC CHEMISTRY. By DR. HERMANN KOLBE, Professor of Chemistry in the University of Leipsic. Translated and edited by T. S. HUMPIDGE, Ph.D., B.Sc. New York, John Wiley & Sons. 8vo. $2.50.

English readers will welcome this translation of the elementary text-book of one of Germany's foremost chemists, representing as it does the course of instruction followed in many of the German schools. The descriptive portions of the work are full and excellent, but the theoretical portions are not always as clear as could be desired, and are in some cases not strictly in accord with facts. "A salt is the substance produced by the union of a base with an acid" is a definition leaning rather to the old dual hypothesis than to an interpretation of the actual phenomenon occurring in the formation of a salt, and gives no idea as to the structure of salts. "Halogen bodies" and "haloid salts" are terms which would better disappear from chemistry than be perpetuated in standard text-books. Is it true that "the atom of oxygen possesses *two points* of attraction," while the atom of hydrogen possesses but one?

This book will prove of value to the student of chemistry, and as a small work of reference; to the general student, and especially for medical students, it is too full and laborious, although the reading is by no means difficult.

The illustrations, press-work, and binding are highly commendable.

G.

GLEANINGS FROM EXCHANGES.

MICROCOCCI IN RELATION TO WOUNDS, ABSCESSES, AND SEPTIC PROCESSES.—In a report to the Scientific Grants Committee of the British Medical Association, Dr. W. Watson Cheyne gives the details of some important experiments, the results of which he summarizes as follows:

"1. There are various kinds of micrococci found in wounds treated aseptically, differing markedly from each other in their effects on animals. They agree in growing best at the temperature of the body, and in causing acidity and sweaty smell in the fluids in which they grow. The experiments show that cultivations may be carried on in fluids with accuracy, provided the precautions mentioned be observed.

"2. The micrococci tested in these experiments grew best in materials exposed to oxygen gas. They grew only with difficulty in the absence of oxygen. Eggs were not good pabulum.

"3. Their effect on animals was not altered by growth with or without oxygen.

"4. The effects of these micrococci on rabbits and man were not similar, some of the most virulent forms for rabbits causing no deleterious effect in wounds in man.

"5. The kidney is apparently an important excreting organ for organisms.

"6. Organisms not capable of growing in the blood may yet cause serious effects by growing in the excretory canals. This may explain some cases of pyelitis.

"7. Where an organism is not markedly pathogenic, it may be necessary to introduce a large quantity before morbid changes are set up.

"8. Suppuration is not always due to micrococci; it may be caused by chemical irritants, such as croton-oil.

"9. Micrococci are always present in acute abscesses, and are probably the cause of them.

"10. In some cases, the micrococci are the

primary cause of the inflammation and suppuration, as in pyæmic abscesses; generally, however, they begin to act after inflammation has been previously induced.

"11. This inflammation may be caused by an injury, by the absorption of chemically irritating substances from wounds, by cold, etc.

"12. There are several different kinds of micrococci associated with suppuration.

"13. Micrococci cause suppuration by the production of a chemically irritating substance, which, if applied to the tissues in a concentrated form, causes necrosis of the tissue, but, if more dilute, causes inflammation and suppuration.

"14. The conditions in wounds and abscesses are not the same, inasmuch as in the former there is opportunity for mechanical and chemical irritants to work.

"15. There is no reason for denying the existence of 'antiseptic suppuration.'

"16. Tension may also cause suppuration, but it is perhaps most frequently aided by the growth of micrococci. These organisms need not be of a very virulent kind. It is also probable that the products of inflammation are themselves irritating and capable of exciting or keeping up inflammation.

"17. The micro-organisms of septicæmia, of pyæmia, and of erysipelas, are different from one another and from those of abscesses. In erysipelas, the micrococci grow in the lymphatic spaces. In pyæmia, they grow in the blood to form colonies and emboli. In septicæmia, they may only grow locally, the symptoms being due to the absorption of their ptomaines; or if they grow in the blood they do not form colonies and emboli. Septicæmia may also be due to other organisms besides micrococci.

"18. There are no facts to support the view that it is the same micrococcus which, under different conditions, causes these various diseases. The experiments of conversion of innocent into malignant forms, and *vice versa*, are unreliable."—*British Medical Journal*, October 4.

THE CAUSE OF CHOLERA.—A member of the Marseilles Cholera Commission has furnished the following summary of its conclusions thus far:

"1. The cholera is transmissible to the rabbit, as demonstrated by injection into the veins of the blood of a cholera-patient at the algid period. The rabbit died in twenty-four hours, with lesions entirely like those of cholera. 2. By cultivation, this blood after a few hours loses its infectious properties. 3. Injections of choleraic blood in the period of reaction, or a very advanced algid period, produce no effect. 4. The perspiration of a cholera-patient, injected into the veins, does not transmit cholera. 5. The stomachic or intestinal dejections, or the gastro-intestinal contents (the last full of comma-bacilli), may, after filtration, be injected with impunity into the cellular tissue of the peritoneum, the windpipe, the intestines, the rectum, and even into the blood. 6. Comma-bacilli taken from the intestines of a cholera-patient may be introduced into the intestines of a rabbit, and multiply there for more than eleven days, without producing any choleraic symptoms, and without necropsy revealing the anatomo-pathological lesions characteristic of cholera. 7. There is thus every proof of the non-specificity of the comma-bacillus. We experimented on bacilli taken from the intestine, and with dejections kept from two to twelve days, the results being always negative. Everything also proves that this bacillus does not produce in the intestine toxical ptomaines which would be the cause of poisoning,—namely, the lesion of the blood. The inference from more than fifty of these experiments is the non-contagiousness of cholera, which we maintained from the very opening of the discussions. 8. The minute examination made by us of the heart and large venous vessels of cholera patients enables us to affirm that there is no phlebocarditis in cholera, as alleged by Morgagni, and still maintained by many enlightened physicians. 9. Bulbar and medullary lesions, or those of the solar plexus, appear to us to be all secondary lesions. 10. In our opinion, the initial lesion of cholera takes place in the blood. 11. It essentially consists in the softening of the hæmoglobin, which makes some corpuscles lose first their clear shape, the fixity of their form, and the faculty of being indented. These corpuscles adhere together, lengthen out, stick together, and, in very rapid cases especially, some are seen which are quite abnormal, while others appear quite healthy. 12. The entire loss of elasticity of the corpuscle (which is shown by the preservation of the elliptic form when it has been stretched out) is, in our view, a certain sign of the patient's death. To stretch out a corpuscle, it is merely needful to alter the inclination of a plate on which a sanguineous current has been established in the field of the microscope. The fluid column stops at one point, whereas the rest continues to flow. An elongation of the intermediary corpuscles results, and then a rupture of the column. In the gap thus formed are some scattered corpuscles. If these revert to their primitive form, the patient may recover. If they keep the elliptic form, we have seen death follow in every case, even if the patient's symptoms were not serious at the time of the examination of the blood. At the outset, and in the rapid cases, which give the clearest results, corpuscles remaining healthy are seen alongside the unhealthy ones, and assume the shape well known in heaps of money, or maintain their liberty. When currents are created in the field of observation, the columns of healthy,

or less unhealthy, corpuscles remain stationary, or nearly so; whereas the unhealthy corpuscles flow between the columns or the stationary masses like fluid lava. This we believe to be the characteristic lesion of cholera. By hourly examination of the blood of cholera-patients the progress of the malady can be mathematically followed. First some corpuscles are unhealthy, then one-third, then half, then two-thirds, and lastly death supervenes. A very important fact in our view is that all the corpuscles are not simultaneously affected. We debar ourselves from substituting a fresh hypothesis for all those we have overthrown. We confine ourselves to saying that we know better than our predecessors what the cholera is not, but we do not know what it is."

Treatment of Lupus by Pyrogallic Acid and Mercurial Plaster. — Dr. Schwimmer reports (*Wiener Med. Wochenschrift*) that after trial of the various methods of treatment upon lupus patients, he has found none which, *when employed singly*, can be pronounced suited to every case. Severe local measures are capable in certain cases of doing more harm than good. Among the most useful means of treatment must be reckoned pyrogallic acid. Applied in the form of an ointment (10 to 15 per cent.) three or four times daily, it soon transforms the morbid growth into a pulpy, grayish substance. Although the cicatrix looks clean after this treatment, it almost always contains tubercles, which in many cases renew the disease. To prevent this result he hit upon mercurial plaster, which he employed in conjunction with the former. The pyrogallic acid is seldom able to produce the total destruction of the lupus tissue alone, and it is well known that the gray plaster has little influence upon the lupoid infiltration by itself; but by using the acid to destroy the lupus tissue, and the plaster afterwards to promote absorption, they act very efficiently. In a series of very malignant cases he pursued with success the following course:

For several days after admission the diseased surfaces were kept completely covered with vaseline smeared on cloths, in order to facilitate the removal of all secondary morbid products, such as scabs, etc. A ten-per-cent. pyrogallic ointment was then applied over the same area, and renewed two or three times in the twenty-four hours. This dressing was employed from four to six days, or, in cases where the cutaneous tissues were insensitive, for six or seven days. On its removal, vaseline was again applied for one day, after which the entire suppurating surface was covered with mercurial plaster. Healing began in from ten days to a fortnight in most localities, but isolated nodes and tubercles could still be detected in the cicatrized integument. Pyrogallic acid was now once more applied for three or four days, causing renewed suppuration of the partly-healed infiltrations, while those more firmly skinned over remained unaffected. When treatment was repeated, so much pain in many cases was experienced on the second day that mercurial plaster had to be at once substituted for the ointment; but if this was not the case, the latter was left on for two days longer. The gray plaster was allowed to remain—being changed once daily if the suppuration was trifling, twice or thrice if it was more profuse—until cicatrization was complete, which sometimes required four weeks. When the complaint was peculiarly indolent and obstinate, the same process was gone over for a third time, but treatment never extended further than this.

An accurate and unprejudiced comparison of the results obtained in this way, with those following other methods, has proved decidedly favorable to the former. A speedier and much better resolution of the most advanced and wide-spreading morbid growths was found to occur under the combined pyrogallic and mercurial treatment, than could have been brought about by the united agencies of scarification and the thermo-cautery.

In conclusion, he states that, in order "to make our estimate more precise, and to obviate any misconception which might cause the means I have recommended to be regarded in the light of a *lupus-panacea*, I present the following summary of the objects which they may reasonably be expected to accomplish:

"1. The severest and most extensive forms of lupus—those hitherto most difficult and frequently impossible of management—may often be essentially ameliorated by these simple and comparatively painless procedures.

"2. The application of mercurial plaster, immediately after several days' use of pyrogallic acid, is able to bring about complete absorption of the tubercles and infiltrated cells at some points, while at others it is remarkably effective in arresting the morbid growth and forming complete and smooth cicatrices, results which are not attained by the use of either remedy alone. The combined treatment may be employed two or three times in succession without any inconvenient consequences.

"3. The more circumscribed forms of lupus are *less* amenable to this method than the diffuse, serpiginous, and ulcerated varieties,—perhaps for the reason that in the latter the corium affords a less congenial breeding-place for the morbific cells. Yet sometimes, in these same cases, better results are obtained through a previous deep scarification of the affected parts, although scarification alone will prove entirely ineffectual.

"4. The duration of treatment is shorter than under the other methods, not exceeding three or four months in the worst cases.

"5. Relapses are to be looked for here no less than after other processes, but are least to be apprehended when the treatment has been thoroughly carried out,—*i.e.*, has terminated in uniform and complete cicatrization.

"6. This method is indicated in the most extended forms of lupus, whether occurring on the face, the body, or the extremities, and is especially suitable in neglected cases which have received no previous treatment.

"7. The affected surfaces, after healing, retain their redness for a considerable period. The discoloration gradually fades, however, and its disappearance can sometimes be hastened by using an ointment of bismuth or zinc."—*Glasgow Medical Journal*, October.

ARE HARMLESS MICRO-ORGANISMS EVER CONVERTED INTO DISEASE-GERMS?—In Dr. Klein's report to the medical officer of the Local Government Board, this distinguished and skilful investigator discusses the theory of the attenuation of virus, and that which has been advanced of late, whether or not a pathogenic organism can be developed from a non-pathogenic one. Buchner having declared that the bacillus of hay-infusion could be converted into that of anthracæmia, Dr. Klein demonstrates the fallacy of this, and shows how the mistake was probably committed. The statement that the jequirity bacillus is a derivative of an ordinary bacillus has been disproved by a number of other experimenters besides Dr. Klein, and the other view, that ordinary mould fungus when cultivated at high temperatures and in alkaline media can be converted into pathogenic material, has also been denied by Gaffky, Koch, and Leber. The spores which flourish under such circumstances are not spores of common mould, but of certain species of aspergillus, which is known to possess pathogenic qualities. With regard to the theory of attenuation, Dr. Klein does not agree with M. Pasteur in his statement that a culture of bacillus anthracis which has become inactive for sheep will yield further cultivations of the same character. Klein, on the contrary, declares that such cultures, under favorable circumstances for development, always regain full virulence. Dr. Klein attributes the diminished virulence to some collateral product which exercises an inhibitory effect upon the development of the organisms: when fresh culture-fluids are inoculated with these enfeebled cultivations, however, these new fluids at once attain full virulence. The substances which exercise an inhibitory influence are supposed to be analogous to the aromatic bodies which come into existence during the course of ordinary putrefaction. The question of the relation of micro-organisms to each other, as well as to diseased conditions, is yet, to a great extent, in a confused condition for the want of more knowledge of the natural history of micro-organisms. In these reports Dr. Klein has contributed the fruits of much laborious investigation to elucidate the subject.—*British Medical Journal*, October 11.

THE QUESTION OF HOME STUDY BY SCHOOL-CHILDREN.—An English court has recently decided that there can be too much study on the part of scholars, under this state of facts: A teacher had prescribed certain lessons which would have to be learned at home, and when the scholar had failed to commit them to memory he inflicted punishment, the character of which is not stated, but which gave rise to a charge of assault and battery against the teacher. The case came before two courts for judgment, and both of them decided that "home lessons set by teachers cannot be enforced." The question of the propriety of giving lessons which must be studied at home, especially in the case of young and growing children, has been very often considered by writers on health subjects, but the legal aspects of the case have not been brought up frequently, and, so far as is known, not at all in this country. The question, if it arose at all here, would come up in connection with the public schools, as there would be no jurisdiction over private schools in this regard. Should it be settled as the law that lessons must not be given requiring home study, it would necessitate having ample time for study during school hours in addition to recitation hours, and it may be a question whether this lengthening of school hours would not be as injurious to health as study at home.

BULLET-WOUND OF THE BRAIN, WITH RECOVERY.—The inhabitants of Uruguay, from their out-door life and exemption from the debilitating influences of high-pressure civilization, possess wonderful recuperative power when injured. Dr. H. Parsons reports a case of a girl, thirteen years of age, who was shot by a playmate with a small-calibre revolver; the bullet entered the mastoid process of the right temporal bone, and took a course inward with a slight downward direction. A probe was introduced six inches into the wound, when it impinged upon a hard substance, which might have been either the ball or the opposite side of the skull. The patient fell as soon as she was shot, but recovered consciousness within an hour, when there was internal strabismus of the left eye and complete loss of power over the left arm and leg, but without being accompanied by loss of sensation. There was considerable hemorrhage from the site of the injury, which was situated just behind the right ear. The wound was dressed with iodoform, cotton wool, and cold compresses. A few doses of bromide of potassium were given internally. The dressing was removed in a few days, when the wound was found to be healed, without any pus or surrounding inflamma-

tion. She was out of bed in a week, and in a month had regained the use of her left leg, and a few weeks later of the left arm. She is now, eighteen months after the accident, apparently perfectly well.—*British Medical Journal*, October 18.

Practical Hygiene.—Dr. Louis W. Atlee contributes a timely article to the October issue of the *Journal of the Franklin Institute* upon "Our Clothing and Our Houses," in which the wardrobe and tenement are submitted to critical examination, and some popular errors and defects condemned. Clothing should protect from the weather and retard heat-radiation from the body without too greatly interfering with the excretory functions of the skin or depriving the body of access to the fresh air. Houses should likewise aid in maintaining the normal temperature, furnish protection from storms, and yet not deprive the organism of oxygen. Dampness is a fruitful source of sickness, and when filth and overcrowding occur under certain conditions of heat and moisture, epidemic disease finds a congenial breeding-place. Many tenement-houses and even private dwellings appear to have been constructed with almost criminal disregard to the health of the occupants. We think that the attention of the public cannot be too strongly or too frequently directed to the fearful penalty which must follow disobedience of the first principles of sanitary science.

Jequirity in Skin-Diseases.—Dr. J. Shoemaker (*Lancet*, August, 1884, p. 185) contributes an able article on "Jequirity (Linnæ): and its Use in Disease of the Skin." Cases are cited, showing the results met with in the treatment of ulcers, lupus, etc. The author sums up by pronouncing jequirity a most powerful agent, applicable to most cases of unhealthy ulcerating and granulating conditions. It exercises a destructive tendency, followed by a constructive change, which leads to a rapid development of healthy tissue. The remedy should be applied with caution, as it may give rise to alarming symptoms, such as erysipelatous inflammation, and in weak and irritable patients to great constitutional disturbance. These symptoms, however, will speedily subside with proper attention and on the drying of the crusts. To prepare a proper solution of the beans, the following directions are given. "Two hundred grains are decorticated by being slightly bruised and cracked in a mortar, the red hulls are carefully picked from the cotyledons, and, in a bottle, covered with distilled water. They are thus macerated for twenty-four hours, when they are again transferred to a mortar and reduced to a smooth paste, and then sufficient water is added to make the whole weigh eight hundred grains." The emulsion is then applied to the ulcers, etc., by a camel's-hair brush. Several strikingly successful cases of lupus, scrofulous, indolent ulcers, venereal and epithelial ulcers, are recorded, illustrating the great value of the drug in such cases.—*London Medical Record.*

Fever of Growth.—In a paper published in the *Gaz. Hebdom. de Méd. et de Chir.*, No. 34, 1884, the author reports several cases of this affection, which has been already carefully described by Bouilly, Guillet, and others. It is most frequent between the ages of seven and fifteen, and seems to be generally caused by some unusual fatigue or exertion. The chief symptoms are fever, pain about one or more joints, and rapid increase in length of the body. The fever varies in degree, duration, and character, but the temperature generally reaches 40° C. (104° F.). The pain, which is much increased by pressure, is localized in some typical situations, such as the epiphyses of the long bones, and more especially of the femur. There may be some effusion into the neighboring joints, but never to any considerable extent. The third symptom is sometimes very marked, and Auboyer has reported a case in which the patient had grown fifteen centimetres in two months. According to M. Reclus, the disease is a mild form of osteomyelitis. The diagnosis requires to be made chiefly from acute rheumatism and from destructive inflammation of the joints. —*London Medical Record.*

The Use of Resorcin in Skin-Diseases. — Andeer (*Monatshefte für Prakt. Dermatologie*, No. 5, 1884) has found resorcin to be a valuable remedy in eczema. He relates the history of a case in which a boy, 18 months old, suffered from a painful eczema of the head and face, which prevented him from either laughing or crying, and rendered restraint necessary to prevent his tearing himself. The treatment consisted in rubbing in vigorously, once a week, an ointment of resorcin with vaseline, beginning with five per cent. and going up gradually to eighty per cent. in strength. The disease yielded entirely to this treatment.—*London Medical Record.*

Cholera.—The sudden and extensive outbreak last week in the city of Paris, after the epidemic in the south of France had been officially decided to have reached its end, gives an additional argument to those who have all along maintained the doctrine of the essential identity of the present with former epidemics of Asiatic cholera, and is a warning to us to put our houses in order for the visitation, which will in all probability be upon us early next year. We hope that proper hospital arrangements will be made to accommodate a large number of sufferers who may suddenly claim medical care, as they did in former epidemics.

MISCELLANY.

PENNSYLVANIA HOSPITAL.—On last Monday evening a notable ceremony was held at the Pennsylvania Hospital, the occasion being the restoration, after an absence of fifty years in another department of the institution, of the celebrated picture of Christ Healing the Sick in the Temple, which had been originally painted for and presented to the hospital by Benjamin West. This canvas is now most appropriately hung in the clinical amphitheatre, facing the audience, over the doorway through which the patients are brought. Dr. Thomas G. Morton, of the hospital staff, upon the unveiling of the picture, gave a brief but interesting account of its history, and was followed by Mr. John B. Garrett, representing the Board of Managers, in an able address, in which the growth of the hospital and its present usefulness were presented. A large audience of invited guests of both ladies and gentlemen was present.

THE MEDICAL JURISPRUDENCE SOCIETY OF PHILADELPHIA, at its stated meeting held November 11, considered some questions of present interest connected with a recent criminal case before the courts, in which a prisoner on trial for the murder of his keeper had set up the plea of insanity. Two papers were read,—one by Dr. Charles K. Mills on the case of Joseph Taylor, the other by Dr. H. C. Wood on "The Absurdities of the Law as Illustrated in the Taylor Case." An interesting discussion was held, in which the President, George W. Biddle, Esq., District Attorney Graham, Drs. Robinson, Packard, and Cohen, and Messrs. Carson and Shapley participated.

POISONOUS CHEESE.—Cases of cheese-poisoning are attributable, according to Dr. Vaughan (*Proc. Am. Pub. Health Assoc.*), to a chemical substance soluble in alcohol, the production of which is attributable to the rapid growth of the Bacillus subtilis. As it is present in new cheese, the difference between the poisonous and non-poisonous is one of degree rather than of kind.

HYDROCHLORATE OF COCAINE, the new local anæsthetic (in four-per-cent. solution) has been received and is for sale by Eisner & Mendelson, importers, No. 320 Race Street, Philadelphia.

DR. HENRY LEFFMANN has been appointed Physician to the Port of Philadelphia by Governor Pattison.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM OCTOBER 26, 1884, *TO NOVEMBER* 8, 1884.

ALDEN, C. H., MAJOR AND SURGEON.—In addition to his duties at Fort Snelling, Minnesota, to perform the duty of attending-surgeon at Department Headquarters. S. O. 127, Headquarters Department of Dakota, October 23, 1884.

SPENCER, W. C., MAJOR AND SURGEON.—Ordered to Fort Trumbull, Connecticut, for duty as post surgeon, relieving Assistant-Surgeon Wm. J. Wilson, U.S.A., who will report at Department Headquarters and await further orders. S. O. 227, Department of the East, November 5, 1884.

TOWN, F. L., MAJOR AND SURGEON.—Assigned to temporary duty as post surgeon, Fort Clark, Texas. S. O. 145, Department of Texas, October 27, 1884.

BENTLEY, EDWIN, MAJOR AND SURGEON.—To be relieved from duty at Fort Clark, Texas. S. O. 145, Department of Texas, October 27, 1884.

WILSON, W. J., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Trumbull, Connecticut. S. O. 220, Department of the East, October 27, 1884.

CORBUSIER, W. H., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty at Fort Bowie, Arizona Territory. S. O. 99, Department of Arizona, October 22, 1884.

CORBUSIER, W. H., CAPTAIN AND ASSISTANT-SURGEON.—Ordered to Fort Grant, Arizona Territory, for duty as post surgeon. S. O. 102, Department of Arizona, October 30, 1884.

LA GARDE, L. A., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty at Fort Ellis, Montana Territory, relieving First-Lieutenant G. E. Bushnell, Assistant-Surgeon U.S A., who, upon being relieved, will report for duty at Fort Snelling, Minnesota. S. O. 126, Department of Dakota, October 22, 1884.

HOPKINS, WM. E., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Ordered to Fort Lowell, Arizona Territory, for duty as post surgeon. S. O. 102, Department of Arizona, October 30, 1884.

EGAN, PETER R., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Fort Lowell, Arizona Territory, and ordered to Fort Bowie, Arizona Territory, for duty as post surgeon. S. O. 102, Department of Arizona, October 30, 1884.

EVERTS, EDWARD, FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 107, Headquarters Division of the Pacific, October 21, 1884.

MCCAW, WALTER D., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Ordered from Fort Craig, New Mexico, to Fort Wingate, New Mexico, for duty. S. O. 92, Headquarters District of New Mexico, October 21, 1884.

LIST OF CHANGES OF STATIONS OF NAVAL MEDICAL OFFICERS FROM OCTOBER 26, 1884, *TO NOVEMBER* 8, 1884.

Surgeon GROVE S. BEARDSLEY, to Washington, D.C., for examination preliminary to promotion, and as to qualifications for sea duty, October 31, 1884.

P. A. Surgeon THOMAS C. CRAIG, to the "Alliance" for temporary duty, October 31, 1884.

P. A. Surgeon JAMES E. GARDNER, to the Naval Hospital, Norfolk, Va., October 28, 1884.

P. A. Surgeon JOHN H. HALL, from the Naval Hospital, New York, to the Navy Yard, Mare Island, California, October 29, 1884.

ORIGINAL COMMUNICATIONS.

REMARKS ON CLINICAL CASES.

Delivered at the Pennsylvania Hospital, November 15, 1884,

BY J. M. DA COSTA, M.D.,

Professor of Theory and Practice of Medicine in the Jefferson Medical College.

Reported for the PHILADELPHIA MEDICAL TIMES.

THE TREATMENT OF HYPERPYREXIA BY COLD APPLICATIONS TO THE ABDOMEN.

GENTLEMEN,—The case now before you is one of typhoid fever, only remarkable for a sustained high temperature persisting in spite of various remedies. The temperature in the morning was 103° F., and occasionally 102°, in the axilla, but for nearly a week the evening temperature remained at 104°; one night it was 104.8°. As there had been no marked exacerbations in the temperature, we looked upon it as a case of grave character, on account of the sustained fever. With reference to the intestinal lesions, as manifested at least by the occurrence of symptoms of bowel-disorder, they were not severe: he had only three or four stools a day. The eruption was well defined, but there is nothing in the case to which I wish to call your attention besides the temperature record.

Let us see his present condition. His temperature this morning is 100½°; last night it was 101½°. I therefore think that the disease is yielding. The bowels have not been opened for thirty-six hours, and tend to constipation. He is very deaf, but obeys intelligently when I can make him hear. His tongue is moderately dry and slightly fissured; it is tremulously protruded. I want you to observe this cracked, dry condition, with the yellowish coating upon it: though it is not very dry, it still impresses you as a dry tongue. His abdomen is rather prominent and tender; a few spots of eruption are still visible upon the surface. There has been some atony of the bladder, so that the urine has had to be frequently drawn with the catheter. Examining his heart, I notice that there is almost complete extinction of the first sound; it can just barely be heard. The pulse beats now only one hundred in the minute, even with the excitement of coming before you; but, as I see upon the record, it has never been a rapid pulse. It is compressible, but has decidedly more volume than it had a few days since. His general condition is improving with the reduction in the temperature. He has been taking dilute muriatic acid (gtt. v) and turpentine (℥x) every two hours. He also takes twelve grains of quinine daily; and six ounces of wine and six of whiskey: therefore he is freely stimulated. His food consists of milk and beef-tea, two pints of each in the twenty-four hours.

Now I have given you a statement of his treatment, with a single exception, and that is what I wish to develop in our discussion,—viz., the treatment of the high temperature. When I found that this man had, a week ago, an evening temperature remaining persistently at 104°, I tried to reduce it by large doses of quinine,—sixteen grains daily; and on one day he took ten grains morning and evening. He was also frequently sponged with cold water. The effect was but slight; the temperature remained high. I then directed that cloths wrung out of ice-water should be laid upon the abdomen until the desired result was obtained. It was found that this was more efficient, and the temperature was at once reduced to 100°, so that by this means we were enabled to keep the temperature within bounds, and thus to gain time. We discussed the expediency of putting him in a bath, but, as he was very weak, and the bath-room is some distance from his bed, rather than subject him to the risks of so much handling, we yielded the point, though, if the bath had been more convenient, I would have preferred it. I wish to call your attention especially to the use of ice-water applications to reduce temperature, as a substitute for the large doses of quinine, and cold baths, which are not always convenient. It is a most instructive case. Indeed, I consider that the man's life has been saved by this means. Taking into consideration the rising temperature and the failing circulation, as shown by the impaired heart-sounds, it did seem likely that the case would not get well. I would also call your attention to the fact that in this case the quinine failed to reduce the temperature. It does not often fail, but it did here.

Another point is this deafness which you have observed. I almost had to shout to him before he put his tongue out. The resident physician tells me that he has been so ever since he came in; therefore it was not the effect of the quinine. Deafness in typhoid fever is not uncommon, and I may state that it does not contra-indicate the use of quinine; by no means. It is due to the state of the blood and the impaired nervous system. We also note here that he has a constant tendency to stupor, is rather drowsy and heavy; he sleeps well at night without opium; he has not been delirious, and has not suffered with headache. The deafness, therefore, is the only symptom referable to the nervous system. There is very little if any jerking of the tendons or tremor.

Now, gentlemen, with regard to the treatment, I shall make a slight modification. Quinine need only be given in tonic doses. We will order him to take eight grains daily. The dry tongue indicates that the turpentine is still useful; the amount of acid is so small that it does not make much difference whether it be continued or not, but, as it is grateful to the stomach and aids digestion, we will continue it also. Sponging of the general surface with water will be done several times a day, as heretofore; and if the temperature again rises we will return to the ice-water applications. With regard to the amount of stimulant, although it seem large, yet I will not yet reduce it, on account of his dry tongue and weak heart. I think that just now it would be dangerous to make any change.

HEART- AND KIDNEY-DISEASE DEPENDENT UPON LEAD-POISONING.

I made some remarks upon this case at the last clinic. I then told you that it was a case of lead-poisoning, heart-disease, with lung-complication and contracted kidneys. He is a fresco-painter, 48 years of age, and told us that he had had several attacks of lead colic from the inhalation of white lead, which he sometimes uses in his business to dust on a fresh-painted surface. He had the blue line upon his gums. He was vomiting at our last meeting, and I gave him, as you remember, a mixture of carbolic acid (gr. $\frac{1}{4}$), morphia (gr. $\frac{1}{32}$), in equal parts of mucilage of acacia and peppermint-water. Now his sick stomach has passed away, although his tongue is still coated and his bowels are constipated. He has also been taking strychnia (gr. $\frac{1}{50}$, t.i.d), which appears to have been useful, as he says that he feels better.

I find, upon listening to his chest, that he has a dilated heart, for which the strychnia is pre-eminently a good remedy, and, moreover, it acts as a tonic upon the nervous system, and locally upon the digestive apparatus. The question now is, Is the dose large enough? I think not. We will make it a thirtieth of a grain three times a day. Just here also arises this question, whether or not, considering the state of the kidneys and the fact that his stomach is now in better condition, it is advisable to give him something besides to act more directly upon the kidneys. I think so. We will give him Basham's mixture, two drachms thrice daily, and if we find that it is tolerated by the stomach we can increase it to a tablespoonful.

I will now call your attention to some interesting points in the pathology of this case. First, we have the history of lead-poisoning, his statement being that he believed that it entered his system by inhalation while dusting on white lead with his hands in fresco-painting. Lead enters the system by many different routes,—through the lungs, as well as through the skin. People who labor in lead-works sometimes come home and eat with dirty hands, and thus introduce the lead into the stomach, or it may be in the drinking-water. One or two small doses of lead of course do not do much harm, but the persistent, continuous introduction of lead produces poisoning. In this case it may have been introduced by the bronchial mucous membrane.

This was one of the points. The others are these: What connection exists, if any, between the structural lesions which we find here in the heart and the kidney? Lead is a factor in the production of disease of the kidney which is often overlooked. Lead produces chronic renal disorder, leading to contracted kidney, and persons who drink water from lead pipes often get Bright's disease in this way. I cannot tell you how many cases I have seen of this kind, since my attention was first directed to this subject, where chronic tubal nephritis had been set up by the action of the lead. It causes a slow process of inflammation in the kidneys, leading to degenerating epithelium and increase of connective tissue, with secondary changes, the most marked being contraction.

As regards the disease of the heart, it is certain that similar changes to those in the kidney may be set up in the walls of the heart, connected with its growth, causing either atrophy or hypertrophy of muscular structure with or without increase of fibrous tissue as a result of the presence of lead in the system. The lung-complication is due to passive congestion, owing to the state of the circulation and heart-failure, and this is also the explanation of the gastric disturbance. You possibly may think that I might improve on this treatment by giving iodide of potassium instead of Basham's mixture, but I am quite sure that the stomach will not tolerate it at present. I may, however, order it should he seem able to bear it.

ACUTE ERYSIPELAS: REMARKABLE RESULT FROM PILOCARPINE.

I have here a case to show you which I think will interest you, as it brings out rather a novel treatment of erysipelas. I intended to exhibit this to you this morning as a case of erysipelas, but I find that the erysipelas is gone. I, therefore, can only speak of the treatment, which has proved more quickly efficacious than I supposed it would.

This man, B. K., 32 years of age, a fireman, was admitted only day before yesterday. This is the record upon admission: "He says that he was quite well yesterday (November 12), but did not go to work, as he was celebrating the election. In the evening, according to his statement, he was not drunk, though he had been drinking a little, and became engaged in a very earnest political discussion, when some one, equally earnest, struck him in the right eye, making a bruise on the cheek and a small lacerated wound of the eyebrow," the evidence of which you may see for yourselves. The man at that time was quite well, although under the influence of liquor. "During the night he had much pain in his eye, and in the morning the eyelids were œdematous and the cheek likewise swollen, red, and burning." When he applied for admission the inflammation was confined to the right side of the face, but it spread rapidly, and the same afternoon both eyes were closed. It is worth adding to this history that he had slept out all Wednesday night after receiving the injury. He was admitted on Thursday morning with erysipelas of the upper part of the face, which was rapidly spreading over the brow. His pulse was 80; temperature, 102.8°; respiration, 22. The urine was examined with a negative result. He was ordered tincture of the chloride of iron, twenty drops every three hours, but only received one dose; as the disease was rapidly spreading, and something was needed to make a prompt impression, I used another and more active agent. This was not the first case in which I had used this remedy, but it was the first in which I obtained such rapid relief. He received hypodermically one-sixth of a grain of the muriate of pilocarpine. The result was remarkable. Here is the temperature record: the temperature fell from 102° to 99½°. He sweat profusely for an hour and a half, and there was no further development of the erysipelas; not only did it not spread further, but what did exist quickly subsided. No local treatment was employed, not even cold applications; therefore whatever success was obtained was from the pilocarpine.

I call your attention to this treatment of erysipelas. I said that it had not been my first case, although it was the most striking case I have seen. As long as five years ago I used jaborandi in the treatment of erysipelas until sweating was produced, and, I thought, with the result of checking further development. In one case with high temperature the disease had already made some headway, and did not subside so quickly. Under the use of iron the disease had not been controlled, but the fluid extract of jaborandi, given every two hours, checked it. I have since used the jaborandi in connection with the iron at times with good results. This is, therefore, not a new treatment with me, as I have used it for some time. Jaborandi and pilocarpine, its active principle, are, of course, similar in their effects.

I have called your attention to this treatment not because I believe that it will be followed by the same result in every case, but because it is worthy of a trial. If you get a case of erysipelas in its beginning, use pilocarpine. It has saved this man a long and dangerous illness, and, as he had been drinking, as he says he had, the results might have been serious. In the use of this treatment it should be borne in mind that, in order to be fully effective, profuse sweating must be produced.

TWO CASES OF MALARIAL CACHEXIA.

I have next to show you two cases somewhat similar, and I will have them both in together. I will be able to merely finish the clinical record of these cases to-day, and must defer any extended remarks upon them to another occasion. They are both instances of malarial cachexia.

This one is Charles Z., 29 years of age, a German, who works at china-painting. He says that he works with metallic pigments, but not with lead. He states that he is temperate, and usually healthy. He came to this country about ten months ago and went to work as a clerk in a store near Charleston, South Carolina, on James's Island. After he had been there a couple of months he suffered with headache, chills and fever, and prostration,—undoubtedly a malarial impression. He took medicine, but with temporary relief, and was obliged to leave. He came to Philadelphia, and two months later he entered this hospital for treatment for intermittent fever, and remained here nearly three months. The notes taken at that time only speak of him as a malarial subject. When he left here he was weak and pale, but did not have chills. Subsequently he suffered with increasing weakness, loss of appetite, and irregular fever. The malarial poison had evidently not been entirely eradicated.

He was re-admitted November 12. Two weeks before this he had headache and fever, and was obliged to give up his work. Upon admission he was slightly jaundiced, as you may still observe. His tongue was pale and his lips looked pale. The appetite was fairly good, bowels generally constipated. His urine contained bile-pigment, but was not albuminous; it was acid, sp. gr. 1020, and contained phosphates in excess. His anæmia is still quite marked. He has a slight cough. I find that his lungs are clear upon percussion; and upon auscultation I can only find anteriorly some harshness of respiration upon the left side, and posteriorly there is diffused harsh breathing on the right as well as the left side. He has, therefore, some catarrh of the bronchial tubes. He has no expectoration. There is no disease of the heart, which, however, is rapidly acting under the excitement of the moment. There is no murmur; the first sound at the left base is murmurish, but is not distinctly replaced by a murmur. The heart is not enlarged. The splenic dulness extends below the margin of the ribs about a finger's breadth; also is it increased towards the median line, below the costal border. It does not extend markedly upwards. Hepatic dulness is very slightly increased over the left lobe. There is no ascites.

A microscopic examination of the blood showed that the number of the cells is reduced, while the relative proportion of the white and red corpuscles is preserved, and the corpuscles are not changed. The case is one of pure anæmia accompanying malarial cachexia with slightly enlarged spleen. This man is taking at present sulphate of iron with carbonate of potassium (gr. jss each) in a pill three times daily. He has a good appetite, and has had no chill at all since admission; his temperature also is normal. In addition to this treatment, as his condition is good and his bowels constipated, we will give him, in a pill, podophyllin, gr. $\frac{1}{8}$, extract of hyoscyamus, gr. ij, each night, and an additional pill in the morning if needed.

The second case is one which you do not see quite in the intensity that it exhibited upon admission. He entered the ward on November 7. He is 19 years of age, and had worked on a farm near Baltimore until ten weeks before, when he was taken sick with tertian intermittent. This was temporarily stopped by quinine, but afterwards the chills returned each day. The malarial cachexia was marked upon his admission. There was marked enlargement of the liver, the percussion-dulness extending two inches below the border of the ribs. But more marked even than this enlargement of the liver was the enlargement of the spleen, which still exists. The area of splenic dulness extends downwards to within one inch of the crest of the ilium and half-way across to the umbilicus. There is a little general soreness upon pressure over the region of the spleen. The urine has been examined, and, while it is high-colored, it does not contain either bile or albumen. The tongue is clean, moist, and not coated as in the preceding case. Bowels are rather loose now, but were not so upon admission into the hospital. He has no cough. He, too, is anæmic-looking, although not to the degree of the other case. His conjunctiva is clear. He had been taking sixteen grains of quinine daily, which were reduced to ten grains on the 10th, and, as he has noises in his ears,

we will now reduce it to six grains daily. He is also taking Basham's mixture.

What will especially interest you in this case of malarial cachexia and enlarged spleen is that he has marked leucocythæmia. An examination of his blood showed a decided increase in the relative proportion of the white cells: from thirteen to seventeen appeared in each field. So that you have here an illustration of leucocythæmia with malarial cachexia, as you also have one of pure anæmia with malarial cachexia, moderately enlarged spleen and liver, and slight jaundice.

What makes the second case more interesting is that there is an actual decrease of the red blood-cells by about one-third, not only an excess of the white but a decrease of the red. This is his first attack. It is remarkable that such changes should take place in the spleen and blood in the short time that he mentions: probably he had been the subject of chronic poisoning from living in a malarial district, but the disease did not manifest itself openly until the time he stated, when he found himself unable to continue his work.

THE PATHOLOGY OF BRONCHO-PNEUMONIA.

BY FRANCIS DELAFIELD, M.D.,

Professor of Pathology and Practical Medicine in the College of Physicians and Surgeons, New York.

Read before the Pathological Society of Philadelphia, October 23, 1884.

I SHALL offer for your consideration, this evening, some observations on the subject of broncho-pneumonia. I venture to do this for the reason that I believe that this particular lesion suffers from the effects of tradition, from having been called catarrhal pneumonia, and from its relations to pulmonary phthisis. It is also doubtful whether the profession appreciate what a common lesion it is.

I do not mean that the real lesions and symptoms of the disease have not been described. They have been described by different observers; but their descriptions have been, for the most part, fragmentary, and have failed to give a picture of the disease.

The current notions concerning the disease have remained somewhat obscure and indefinite. The prevailing ideas concerning broncho-pneumonia may be stated as follows:

That the terms broncho-pneumonia, lobular pneumonia, catarrhal pneumonia, and capillary bronchitis may all be used to designate the same lesion; although it is customary to use the words broncho-pneumonia and lobular pneumonia when the disease occurs in children, capillary bronchitis when it occurs in adults, and catarrhal pneumonia when it is believed to be a form of phthisis.

That the inflammation begins in the bronchi, extends to the small and capillary tubes, and then to the groups of air-vesicles which belong to these bronchi, and that for this reason the hepatization assumes a lobular form.

That obstruction of the bronchi with inflammatory products frequently produces areas of atelectasis.

That the catarrh may become chronic, the products of inflammation in the air-vesicles undergo cheesy degeneration, interstitial changes be developed in the framework of the lung, and so a form of pulmonary phthisis be produced.

This, I think, is a fair enough example of the ordinary accounts of broncho-pneumonia,—accounts which fail to bring out the essential features of the disease.

Let us, then, turn to the conditions themselves,—to the clinical symptoms and the lesions of broncho-pneumonia, as we all can see them for ourselves.

To approach the subject properly, we must consider the symptoms and lesions of acute bronchitis, as well as those of broncho-pneumonia.

First, then, of *acute catarrhal bronchitis.* This is a disease of very common occurrence, especially in children, but one which seldom proves fatal. Our knowledge of its lesions is derived from exceptionally severe cases, from cases which are complicated by other diseases, and from the symptoms which we observe during life.

The inflammation involves regularly the trachea and the larger bronchi; less frequently the smaller bronchi also. As a rule, the bronchi in both lungs are equally affected.

The first change seems to consist in a congestion and swelling of the mucous membrane of the bronchi, with an arrest of the functions of their mucous glands. This is attended with pain over the chest,

a feeling of oppression, rapid or asthmatic breathing, and a dry cough.

Fever and prostration are present in a degree corresponding to the extent and severity of the inflammation, and to the age of the patient.

After this the mucous glands resume their functions with increased activity, the congestion and swelling diminish, there is a more rapid desquamation of the superficial epithelial cells, an increased growth of the deeper epithelial cells, and a moderate emigration of white blood-cells. Sometimes the red blood-cells also escape from the vessels.

The patient now has less pain and oppression, the cough is accompanied with an expectoration of mucus mixed with epithelium, pus, and sometimes blood. After death, the only lesions visible are the increased quantity of mucus, the growth of new epithelium, a few pus-cells infiltrating the stroma of the mucous membrane, and sometimes a general congestion. If the smaller bronchi are involved, they contain pus-cells.

In a moderate number of cases, especially in very young children, certain accessory lesions are added. There may be a general congestion of the parenchyma of the lung, and even a filling of some of the air-vesicles with inflammatory products. Still further, the filling of the small bronchi may lead to the collapse of the groups of air-vesicles to which they lead, and thus are produced areas of atelectasis, which may be further changed by inflammatory processes.

In acute catarrhal bronchitis, then, the inflammation involves regularly only the mucous membrane of the bronchi; and in this mucous membrane the only changes are congestion, swelling, changes in the epithelial cells, and in the functions of the mucous glands.

As complicating conditions, we may find atelectasis, congestion of the parenchyma, and areas of diffuse pneumonia.

Now let us consider the lesions and symptoms of broncho-pneumonia.

This disease is of common occurrence in children as an idiopathic inflammation, and as a complication of measles, whooping-cough, scarlet fever, and diphtheria. In adults it occurs less frequently; but in them, also, it may be idiopathic, may complicate the infectious diseases, and may follow injuries of the brain and spinal cord. Constitutional syphilis, also, may give rise to broncho-pneumonia, and in pulmonary phthisis this same inflammation constitutes an important part of the lesions.

In children, while the inflammation always presents the same essential characters, yet there is considerable diversity, both in the symptoms and in the lesions, in different cases. Thus, in infants a few weeks old, often the only symptoms are rapid breathing, a febrile movement, prostration, and death.

In older children there are well-marked constitutional disturbances,—fever, prostration, and cerebral symptoms, in some cases the cerebral symptoms being excessively developed. The breathing is rapid. There may be cough. The physical signs are those of bronchitis alone, or of bronchitis with consolidation of the lung. If there is consolidation, it is developed slowly and disappears slowly. Not infrequently successive portions of the lung become consolidated. The disease terminates in the death of the patient, in recovery, or it assumes a chronic character. This disposition of the broncho-pneumonia to become chronic is one of its characteristic features, a feature in which it differs from acute bronchitis and lobar pneumonia. The cases vary, however, as to the degree in which the disposition is carried out.

In some children, the disease, after running its regular course of one or two weeks, subsides: the constitutional symptoms are less marked; the child seems better in every way. But yet the physical signs of consolidation continue; there is still a slight rise of temperature, and convalescence does not fairly begin. In this condition the child may remain for a number of weeks, and then get entirely well, except that the percussion-note and the breathing remain somewhat changed.

In many such cases as these the recovery is permanent, and the child has no further trouble. But in other cases, after the lapse of several months, the child is attacked with acute general tuberculosis. Thus, it is not uncommon, in children's asylums, for an epidemic of measles complicated with broncho-pneumonia to be followed, after the lapse of a year, by an epidemic of acute tuberculosis.

In other children the course of the disease is more protracted. The physical

signs of consolidation continue; there is a febrile movement; the child has no appetite, it gradually emaciates, and dies at the end of several months. These cases resemble pulmonary phthisis in their symptoms, but they are really only examples of a broncho-pneumonia which has become chronic.

In still other children the physical signs and the constitutional disturbances continue, but the child does not succumb to the disease. It continues to live with the evidences of a chronic bronchitis, which go on year after year. So the child may grow up to adult life, sometimes better, sometimes worse, never entirely well. Cough, expectoration, dyspnœa, occasional fever, harass the patient at intervals. The lung becomes more and more solid, the bronchi more dilated, the pleura thicker, and the affected side of the chest more retracted.

In the cases of acute broncho-pneumonia which die within from two days to three weeks there is some variety in *the post-mortem appearances.*

The lungs may be large and well aërated, but on section the cut ends of the medium-sized and smaller bronchi are unusually prominent and thick, and around them are little zones of hepatization of red, or gray, or white color. This appearance of the lung may be further modified by a cylindrical dilatation of the thickened bronchi.

In other cases the lungs are denser and more congested, and a larger or smaller portion of them is consolidated. The consolidation portions are unaërated, dense, and smooth, of red color, or pinkish-gray, or dark red. Or the color may be mottled,—small, rounded gray or whitish areas surrounded by red hepatization.

The distribution and extent of the consolidation also vary. The hepatized areas may be small, encircle the bronchi, and situated at some distance from each other. Or they may, in some one lobe or part of a lobe, be close together, and between them is a more diffuse hepatization, so that this part of the lung may be completely solid.

The appearance of the consolidated lung may be further changed by a cylindrical dilatation of the bronchi.

In still other cases the consolidated portions of lung are of some size and of somewhat regular shape, as if they were portions of lung corresponding to bronchi. These portions are dense, unaërated, of dark-red color, and somewhat shrunken.

If the inflammation has become chronic, then over one lobe or part of a lobe the pleura is thickened, bands of fibrous tissue run into the substance of the lung, and the lung-tissue is dense, hard, and unaërated.

When we examine these lungs more minutely, we notice first some peculiarities which belong to them because they are the lungs of children and not of adults. The bronchi and the connective-tissue framework of the lungs occupy a larger relative space than they do in the lungs of adults, and in any inflammation of the lungs they are apt to take a more prominent share. The air-vesicles are small, and products of inflammation which have been formed within them are absorbed slowly and with difficulty. The walls of the vesicles are lined with a nearly continuous layer of epithelial cells. When the vesicles are inflamed, there is a greater production of new epithelium and a less of fibrin than in adult lungs. The small size of the air-vesicles renders a simple congestion and dilatation of the capillary vessels within their walls a more serious condition than it is in adults. The bronchial glands are more regularly and intensely inflamed. These peculiarities of the child's lung seem to account for its liability to certain forms of inflammation.

The same exciting causes apparently produce in a child under five years of age broncho-pneumonia; in a person between the age of five and fifteen, broncho-pneumonia, or lobar pneumonia; in an adult, lobar pneumonia.

Now let us consider more in detail the lesions of broncho-pneumonia in children.

The trachea and large bronchi are congested and coated with mucus, as in acute bronchitis; but in the smaller, and to a less extent in the capillary, bronchi, the changes are of a different character. In these small bronchi the entire thickness of their walls is infiltrated with cells,—partly new connective-tissue cells, partly pus cells. This change may affect the small bronchi equally in all parts of the lungs, or it may be confined to those situated in one lobe or part of a lobe.

Around every bronchus, of which the walls are infiltrated with cells in this way, is a zone, either of intense congestion or

of pneumonia, the inflammation extending directly outwards from the bronchus to the surrounding vesicles.

In the zones of peri-bronchitic pneumonia, the walls of the air-vesicles are infiltrated with cells in the same way as are those of the bronchi. The cavities of the vesicles are filled with pus and epithelium, or with an organized tissue composed of a basement-substance and cells.

These constitute the essential features of the lesion,—a bronchitis which involves the *walls* of the bronchi, and a pneumonia which involves the vesicles *surrounding* the bronchi, and which produces changes in the *walls* of the vesicles as well as in their cavities, while the inflammatory products within the cavities of the vesicles are not only pus and fibrin, but also organized tissue.

To these essential lesions are often added other accessory changes. The bronchi, of which the walls are infiltrated with cells, may be dilated. Between the zones of peri-bronchitic pneumonia the lung is congested, and there may be areas of diffuse red hepatization, which do not, however, correspond to bronchi. There is often a layer of fibrin on the pulmonary pleura. There may be areas of atelectasis corresponding to obstructed bronchi.

The bronchial glands are swollen, and the seat either of simple or of tubercular inflammation.

When the broncho-pneumonia passes into the chronic condition, the inflammation usually persists only in part of a lobe, or a single lobe, while the rest of the lungs return to a normal condition. In that portion of the lung in which the inflammation persists we find the small bronchi with their thickened walls and their zones of peri-bronchitic pneumonia. The number of bronchi involved may be moderate, and then a section of the lung will look as if it were studded with fibrous nodules. Or most of the bronchi may be involved, the zones of peri-bronchitic pneumonia are close together, and the entire lung-tissue is dense and solid. In either case the bronchi may be dilated and the pulmonary pleura thickened. As the inflammation goes on, its interstitial character becomes more and more marked, until the affected portion of lung becomes converted into a mass of fibrous tissue, in which the bronchi still remain, while the air-vesicles are obliterated. The blood-vessels, however, are for the most part not obliterated, so that the lung does not become necrotic or degenerated. Still, occasionally, areas of cheesy degeneration exist.

These are the characteristic features, then, of the broncho-pneumonia of children.

In adults, broncho-pneumonia occurs in one of four forms: as an idiopathic inflammation of acute and severe type; as a subacute inflammation; as a complication of the infectious diseases and of lesions of the brain and spinal cord; as one of the lesions of phthisis.

1. The acute, idiopathic broncho-pneumonia of adults.

The invasion of this disease is acute and severe.

The patients have rigors, pains in the head, back, and chest, vomiting, and marked prostration. The temperature runs between 102 and 105; the pulse is rapid; the breathing is rapid and unsatisfactory. There is cough, at first dry, later accompanied by profuse muco-purulent and bloody expectoration. There is venous congestion of the skin, albumen in the urine, and cerebral symptoms. When we examine the chest, we find the percussion-note normal, or exaggerated, or dull. There are crepitant, sub-crepitant, and coarse râles, with sibilant and sonorous breathing.

The cases usually terminate fatally in about seven days. After death we find both lungs large, heavy, and congested. There is fibrin on the pulmonary pleura. The trachea and large bronchi are congested and coated with mucus. The smaller bronchi contain pus, their walls are thickened and infiltrated with cells, and around them are zones of air-vesicles, with their blood-vessels gorged with blood, and in their cavities epithelium, pus, and fibrin.

2. *The subacute broncho-pneumonia of adults.*—This is a rare disease; it has a clinical history much resembling that of acute phthisis.

The patients are attacked with prostration, fever, cough and muco-purulent expectoration, dyspnœa, pain in the chest, coarse râles all over the chest, with dulness over the consolidated portion of the lung. These symptoms continue, the patients lose flesh and strength, and die at the end of several weeks.

After death we find fibrin on the pulmonary pleura. The larger bronchi are congested and coated with mucus. There is an irregular, diffuse, red hepatization, mottled with small white nodules, from the size of a pin's head to that of a pea. In the diffuse red hepatization the air-vesicles are filled with pus, epithelium, and fibrin. The white nodules correspond to sections of bronchi with zones of peri-bronchitic pneumonia. These bronchi are of small size, they contain pus, their walls are thickened and infiltrated with cells, and they may be dilated.

In the peri-bronchitic zones of pneumonia the walls of the vesicles are thickened and infiltrated with cells, but the blood-vessels remain pervious and can be injected. The cavities of the vesicles are filled not with pus and fibrin alone, but also with a basement-substance of homogeneous or finely-fibrillated character, in which are embedded polygonal, round, and fusiform cells.

3. *The complicating broncho-pneumonia of adults.*—It is not uncommon for some of the infectious diseases and some of the lesions of the brain and spinal cord to be accompanied by the development of this form of inflammation of the lung.

In typhoid fever we sometimes find a broncho-pneumonia exactly resembling the same lesion as it ordinarily occurs in children.

In pyæmia the inflammation is of the same kind, but is apt to be less extensive, involving only part of one or both lungs.

With lesions of the brain and spinal cord the changes are the same as with pyæmia.

4. *With phthisis*, both acute and chronic, broncho-pneumonia often forms an important part of the morbid changes in the lungs, but yet it is never the primary or the only lesion. It is only one of a number of pathological changes which go to make up the complex whole of pulmonary phthisis.

From what has been said, then, I would draw the following conclusions:

There is a form of inflammation of the lung which may properly be called broncho-pneumonia.

In children it is the most frequent form of pneumonia, in adults it is less common.

It differs from bronchitis and from lobar pneumonia in that the inflammation effects changes in the *walls* of the bronchi and of the air-vesicles, and this peculiar interstitial character of the process exists from the very outset.

The inflammation extends from the bronchi not to the group of air-vesicles into which they lead, but directly outwards to the vesicles which surround the inflamed bronchi, and in these vesicles the walls are changed.

The interstitial character of the inflammation is its most important feature. It accounts for the severity of the symptoms, the frequent long continuance of the consolidation, the dilatation of the bronchi, and for the tendency of the broncho-pneumonia to assume a chronic character.

The complicating tubercular inflammation of the bronchial glands may give rise later to general tuberculosis.

Broncho-pneumonia is not a form of phthisis; it is doubtful if it is ever directly followed by phthisis; but it constitutes a part, and often an important one, of the lesions which constitute phthisis.

I have endeavored to describe in a somewhat incomplete way the characteristic symptoms and lesions of an ordinary disease. I am well aware that I have described conditions which are familiar, and that nothing which I have said has not been said before.

But the very common occurrence of this form of inflammation of the lung renders it all the more important. The varying character of the lesions has confused their essential and their accidental characters, and I think it is worthy of consideration whether the views which I have advanced concerning the pathology of the disease are not the true ones,—namely, that the inflammation is essentially and from the outset an interstitial one, more or less complicated by other conditions.

A NOTE ON KAIRIN.

BY JAMES H. HUTCHINSON, M.D.,

One of the Attending Physicians to the Pennsylvania Hospital.

ALTHOUGH more than a year has elapsed since Filehne called the attention of the profession to the remarkable antipyretic properties of kairin, and although his observations have been fully confirmed by many physicians in Germany, the drug seems to have been resorted to but rarely in this country. In-

deed, I am not aware that previous to my own experiments any trials of its efficacy in the treatment of hyperpyrexia had been made in this city. Kairin was originally made known to us through the experiments of Fischer and Königs, and is one of a series of artificial alkaloids derived from chinolin by the addition of oxygen, hydrogen, and carbonic acid. It occurs in a yellowish-white crystalline powder, of a somewhat pungent bitter taste, which is excessively disagreeable to most patients. Given in doses of from one to one and a half grammes to healthy adults, it has no physiological action and no effect upon the temperature. It also does not produce any unpleasant effects, such as headache, ringing in the ears, or sickness. When, on the other hand, it is administered in hourly doses of half a gramme, in febrile conditions, with the temperature ranging between 103° and 105° F., the temperature is usually reduced in two hours from three to five degrees, and not infrequently falls to normal. The defervescence is generally accompanied by profuse perspiration, which usually continues until the temperature ceases to fall, by shivering, and by a greenish discoloration of the urine. If administered in larger doses (from a gramme and a half to three grammes and a half), it often produces grave symptoms, such as cyanosis, apathy, and subnormal temperature, which necessitate the prompt use of stimulants. Occasionally collapse is produced by it, resembling, it is said by Drs. Freymuth and Polchen, that of cholera Asiatica, but differing from the latter in the sense of vigor felt by the patient, who invariably recovers. Filehne says the temperature is often reduced to 94.6° F. by doses as small as the eighth of a gramme in patients of a slender build or who are emaciated or suffering from hectic fever.

Guttmann has given kairin in cases of pneumonia, measles, phthisis, typhoid fever, scarlatina, pleurisy, peritonitis, erysipelas, ague, septicæmia, and apparently always with advantage. On the other hand, Dr. H. Menche's (of Rheydt) experience with it in the pyrexial stages of pneumonia, pleurisy, and pernicious anæmia was unfavorable, which has been attributed by others to the use of large doses. In rheumatism, he found that its use was followed by diminution of the pain, but not by any reduction in the swelling of the joints. Freymuth and Polchen have prescribed it in relapsing fever, with the following results: When given from the fourteenth day after the first attack of relapsing fever, the second attack occurred as usual, but in a very modified form, with a rigor but no elevation of temperature, and with spirilla in such small numbers that the nature of the attack was barely recognizable. This continued for twenty-five hours, when the kairin was omitted. Two hours afterwards a classical relapse occurred, with a temperature of 104.9° F., and spirilla in abundance.

The first case in which I was induced to try kairin was one of typhoid fever of more than ordinary severity.

The patient, a robust young Irishman, was admitted to the Pennsylvania Hospital in the second week of the disease, and was treated in the usual way for the first week. On the ninth day after his admission, observing that there was little, if any, morning remission, and that the temperature was 103° F., I determined to make trial of the new drug. A dose of eight grains was accordingly given at 1 P.M. on May 5. An hour later, no effect having been produced, a second dose of the same amount was administered. At 3 P.M. the temperature was found to have been reduced to 101° F. At 5 P.M., as the thermometer showed that the temperature had risen again to 103°, a third dose of a like amount was prescribed, with the result of a fall of temperature within an hour to 101⅖° F. At 8 P.M. the temperature had again risen to 103°, and a fourth dose was accordingly administered, and the temperature again reduced one and a half degrees. The exhibition of the drug was followed by depression, by profuse sweating, and, after the last dose, by some muscular tremor. The depression of temperature was temporary, lasting only about an hour. Kairin was not administered again until the fourteenth day after admission, when it reduced the temperature in an hour from 102.5° to 100°. In the mean time, the fever had ceased to be continuous, the morning remissions being as marked as they usually are in the third week of typhoid fever.

In one other case of typhoid fever I gave kairin with as marked results as those just detailed, and it also reduced the temperature very considerably in a case of

malarial fever; but in this latter case I did not like to push it as in the other cases, on account of the extreme debility of the patient.

By the kindness of Dr. J. Howard Reeves, lately resident physician to the Pennsylvania Hospital, I am permitted to refer to a case of sunstroke to which he gave kairin. The patient, who had a temperature of 105°, was conscious, but almost delirious with pain in his head. A cold bath was given to him immediately after his admission to the Pennsylvania Hospital, which reduced the temperature a few degrees. It rose again soon after, and the skin became as dry and burning as before. Eight grains of kairin were then given to him. In an hour his temperature had fallen two degrees, and he was covered with a profuse perspiration. The temperature after this steadily fell, and in three hours had reached the normal.

Observing that profuse perspiration was one of the consequences of its administration in the above cases, it occurred to me that kairin might possess valuable properties as a diaphoretic. With this end in view, I gave it in eight-grain doses to a patient with general anasarca dependent upon disease of the kidney. No sweating followed its use,—a result which was probably due to the fact that the patient was free from fever. It will be remembered that in my opening remarks it is expressly stated that no sweating is produced by its administration in health.

The cases which I have just reported have convinced me that kairin possesses the power of reducing the temperature of the body in fever to an unusual degree, and that it does this with certainty and promptitude, and, it may be added, when moderate doses are used, with safety. One care, however, it is necessary to exercise in its administration, and that is to use fresh specimens of the drug only, as it undergoes change if kept for any length of time. It reduces the temperature much more rapidly than quinia, although the apyrexia produced by it is of much shorter duration than that caused by the latter. It is also capable of depressing the temperature during the evening exacerbations of fever, while the most marked results are obtained, on the other hand, from quinia just before the morning's remission. Its use is also free from some of the objections usually urged against the latter, as it does not give rise to unpleasant effects, such as headache, ringing in the ears, and the like. Although less rapid in its action than the cold bath, it is obvious that it may be administered in many cases in which a resort to the latter would be impossible. The excitement and terror which are often occasioned by the use of the bath, even when it is brought to the bedside of the patient, constitute a positive objection to it, which, to my mind, becomes insuperable in cases in which it is necessary to carry him some distance to a bath-room. It is said to exert a marked and favorable influence over the brain-symptoms which occur in fevers, possessing, in this respect, an undeniable advantage over several of the other antipyretics.

133 South Twenty-second Street, Philadelphia.

REPORT ON MEDICAL AND SURGICAL ELECTRICITY.

BY WM. R. D. BLACKWOOD, M.D.

GALVANISM.

DR. MAX BUCH has called attention to the fact that galvanic irritation of a living muscle always produces an increase of temperature, and has, in this connection, proposed to apply electricity to determine the truth in cases where death is not certain. Although muscular contraction can be produced for a short time after death in certain portions of the body (the deltoid, or quadriceps femoris), no elevation of the temperature occurs after five hours, and he therefore proposes the conjoined application of a delicate surface-thermometer, with the current from, say, five cells. When the mercury has remained stationary for some minutes after applying the thermometer the current is turned on, and at once the column rises in the tube if the muscle is alive, but if death has occurred the temperature remains unaltered. The method may, at rare times, be of value, but other very good indications of death are within reach of practitioners of ordinary skill.

Gibney reiterates, in the *New York Medical Record*, the advantage of the *strong* galvanic current in obstinate sciatica. He applies the positive pole over the nerve at its point of exit at the sacro-sciatic notch, and the negative is placed just above the popliteal space, or, preferably, over the area of greatest pain. The

current is run up to its maximum bearable force and kept there. Referred sensations (paræsthesia) will now be felt throughout the distribution of the nerve. The pain is never so bad from the current as from the neuralgia, and relief is usual from the first. Great care must be observed in precision of application. Cases are given in illustration, and we know, from experience, the value of Dr. Gibney's method; and our own observation agrees with his in several obstinate cases, where every other method of treatment failed.

The galvano-cautery has been lauded by Frolich, of Berlin, in follicular catarrh and trachoma. The reaction is stated to be slight, even when extensive granulations have thus been destroyed.

The cautery has also been quite successfully employed in lupus by Bernier (*Paris Médical*), and Shoemaker, of our own city. One great advantage over jequirity and ordinary caustics is the almost entire absence of acute pain, and another is the decreased probability of auto-inoculation. The incisions usually made by the bistoury have, without doubt, been the means of extending the disease, when carelessly made. It is asserted that the latter procedure has, before now, been the cause of lighting up internal tuberculosis, true lupus being, according to Cornil, a tuberculous disorder of the skin. This theory has received support from good authority at late medical conventions, and if the cautery can compete with older methods of destroying the local affection, which is reasonably certain, the advance in therapeutics is an important one.

The troublesome senile hypertrophy of the prostate is, according to Bredert (*Berlin. Klin. Woch.*), rapidly reduced by electrolysis, the cathode being applied to the gland by insulated needles. Five cases are reported as thus cured, but the account given does not state whether the reaction developed any inflammatory sequelæ. In our own cases, where the ordinary current has been applied *without puncture*, we have repeatedly had to combat considerable irritation of the bladder, though, curiously enough, galvanism has, at times, relieved cystitis promptly which arose from other causes.

GALVANO-PUNCTURE IN ANEURISM OF THE AORTA.

Dr. Francesco Brancaccio reports the case of a man, intemperate, 64, who, on examination, showed a tumor limited above by the upper border of the second rib, on the right by the sternum, on the left by the mammary line, and which was continuous below with the heart. The diagnosis was aneurism of the ascending aorta, and galvano-puncture was practised. Two needles were inserted in the third interspace to a depth of one inch and a fifth, and one inch and a half apart. Fifteen Daniell cells were used (seventeen volts). The first sitting lasted sixteen minutes. The patient was better the same afternoon; the pulse fell from 118 to 90, was stronger, and the tremor was smaller; the respiration was freer and less frequent. Twenty cells were used for fourteen minutes twenty days afterwards, and four applications made the cure complete.

Hydrarthrosis of the knee has been repeatedly relieved by galvanism, and a case is reported by Dr. Castaneo, of Buenos Ayres (*Revue Médicale*), in which a cure was promptly effected after blisters, cautery, and other radical measures failed. Many instances are now on record evidencing the rapid absorption of pleuritic effusions under galvanism, and others of abdominal character (not encysted); hence the success might logically be looked for in any joint-effusion where the integrity of the articulation had not been destroyed.

Silva-Aranjo and Moncorvo communicated their first note on the treatment of elephantiasis by electricity to the Academy of Sciences of Paris in 1880, and to the Academy of Medicine in 1881. More than a century ago Henley treated a case successfully (*Alard, De l' Inflammation des Vaisseaux Absorbans (sic) Lymphatiques, Dermoides et Souscutanés*, Paris, 1824, p. 589). When Silva-Aranjo first applied electricity to elephantiasis of the scrotum, in 1879, he neither knew of this case nor of those of Beard and Rockwell (Tibbits's "Hand-Book of Medical and Surgical Electricity," London, 1877). The authors employ from forty to sixty Trouvé elements, the negative to different affected points, and the positive on the sound skin near by. They sometimes use faradic currents in conjunction, but their reasons for doing so are not apparent. The duration of each application is from fifteen to thirty minutes, and in severe cases electro-puncture with needles is resorted to.

Trials have also been successful in the service of Professor Oliveira Ferjaô, of Lisbon, and are in progress at Vienna, in the division of Professor Kaposi, by Riehl. Their conclusion is that, if not infallible, electricity is certainly the best agent in our hands at present for treatment of this formidable disease. We have no account of the treatment by electricity in this country aside from those already noted, but the frequency of the disease would certainly afford wider experiment than has heretofore been reported.

FARADISM.

The induced current has been used in pleural effusions of varied kind and degree, as reported by a number of Continental authors, and their results agree with our own, so far as hastened absorption of serum was concerned in later stages of acute pleurisy.

In obtaining condensation of the uterus where involution has not progressed satisfactorily after labor, the faradic current is highly recommended by several reporters. Some ten years ago we gave the detailed history of a number of cases of subinvolution treated entirely by electricity, and we are glad now to notice, at last, one of our critics as having been converted after his plainly-expressed disbelief. We have had excellent results always in such cases, and also in hypertrophy of the organ from many other causes, notably from submucous fibroids. Recently a lady who declined surgical measures has parted with her fibroids (two in number) under careful faradization, and this without taking ergot or any other drug.

The ordinary faradic coil as usually wound with a single secondary of a uniform gauge of very fine wire will not answer for treatment of deep-seated visceral organs. An arrangement of multiplex coils of varying specific resistance wire and different area in cross-section of both wire and spool is necessary, as described in another place.* The number of binding-posts in ordinary faradic batteries is no criterion of their value, the secondary being merely looped out at points and connected to these posts. Intensity in such cases is just as well governed by the draw-tube, and accidents from short circuiting in poorly-covered wire are liable in this plan of construction.

Obstinate hiccough is reported as cured by faradism, but the current has failed in our hands, although faithfully tried, in a hospital case, which gave way at last to monobromide of camphor, cannabis Indica, and sumbul.

In psoriasis, acne, and prurigo, faradic currents have been reported, within the past three months, as successful in many cases, some of them inveterate in their severity.

STATIC ELECTRICITY.

In the *Progrès Médical* we find, incident to the phenomena of static electricity, the case of a young woman suffering from ovarian hyperæsthesia and hysteria, who possesses increased bodily electricity. Brushing her hair produces crepitation and sparks, light substances cling to her finger-ends, and dry clothing wraps her limbs so tightly as to impede voluntary movements. The intensity of the phenomenon coincides with her feelings: when highly charged she is well and sprightly; when not, she is dull and depressed. Damp weather disagrees with her, as it does with the static machine, and after repeated discharges she feels exhausted. These phenomena cannot be averted by the wearing of silk underclothing, as might be expected, but the application of the "electric wind" is at once efficacious in restoring her spirits, no matter how much depressed she may at the time be. Our plan of applying the "wind" or "bath" is to insulate the patient, connect the stool with the *outside* of one jar by chain, and then, through a ball rheophore connected with the *outside* of the other condenser, make a thorough "general" application. The jars must be disconnected, and the "brush" made as long as possible, to obtain the peculiar refreshing effect.

Vigoroux contributes to the same journal an article on the prevention of cholera by the use of static electricity. He refers to experiments of Boillot, Angus Smith, and Chapuis, which prove the great disinfecting power of ozone, as produced by the static machine, and the stimulus to nutrition by the electric bath (insulation on platform). He believes that daily baths are the best prophylactics against cholera; but the unreliability of the machines, as generally made, militates against their use

* "The Causes and Treatment of Constipation," Philadelphia Medical Times, July 28, 1883, and Proceedings of the Philadelphia County Medical Society, vol. v. p. 173.

extensively, even if the theory were correct,—which we doubt.

The Toepler-Holtz of James W. Queen & Co., of this city, is the only static-electric machine in our experience which is *uniformly* reliable in all weathers, but it requires care to keep it so in humid summer months if not encased in an air-tight cover. Properly covered and kept *free from dust*, it will work satisfactorily at any time.

EXPERT AND NON-EXPERT EVIDENCE.

BY HENRY A. RILEY, ESQ.,

New York City.

ONE of the most vexed questions in medico-legal matters is the proper weight to be given to expert evidence, and in what respects it is better than non-expert evidence. A short time since there were several articles in one of the leading reviews on this subject, and one or two of the writers took the ground that, on the whole, expert medical evidence was unreliable. This is not the general view, however; and, with proper restrictions, there is no doubt that expert evidence is of as much value as any that can be produced in the trial of a case. There is a great deal of doubt whether the production of expert witnesses by one side or the other to sustain its own case is not a vicious privilege, and the cause of much of the dissatisfaction felt by the public with the whole system. It certainly does not add to the popular respect to see several distinguished physicians testify on a trial that a person is insane, and then to see them followed by several other equally distinguished physicians, who testify to exactly the opposite.

The only remedy, apparently, for this state of affairs is to have the experts called by the court, instead of by a particular side to bolster up its own case. In this way the physician is really independent, and is not rendered partial by the knowledge that his compensation depends upon his taking the view certain lawyers desire.

The courts will, however, admit non-expert testimony, under certain conditions, in cases where it is generally supposed that only professional persons can give reliable opinions. Even in cases where the insanity of a person is in question, such non-expert testimony may be produced. The proper limits of such testimony were settled in a recent case in the United States Supreme Court, where Justice Harlan gave the following interesting opinion: "Counsel for the plaintiff in error contends that witnesses who are not experts in medical science may not, under any circumstances, express their judgment as to the sane or insane state of a person's mind. This position, it must be conceded, finds support in some adjudged cases, as well as in some elementary treatises on evidence. But in our opinion it cannot be sustained, consistently with the weight of authority, nor without closing an important avenue of truth in many, if not every, case, civil and criminal, which involves the question of insanity. Whether an individual is insane, is not always best solved by abstruse metaphysical speculations, expressed in the technical language of medical science. The common sense, and, we may add, the natural instincts, of mankind, reject the supposition that only experts can approximate certainty upon such a subject. There are matters of which all men have more or less knowledge, according to their mental capacity and habits of observation,—matters about which they may and do form opinions sufficiently satisfactory to constitute the basis of action. While the mere opinion of a non-professional witness, predicated upon facts detailed by others, is incompetent as evidence upon an issue of insanity, his judgment based upon personal knowledge of the circumstances involved in such an inquiry certainly is of value, because the natural and ordinary operations of the human intellect, and the appearance and conduct of insane persons, as contrasted with the appearance and conduct of persons of sound mind, are more or less understood and recognized by every one of ordinary intelligence who comes in contact with his species. The extent to which such opinions should influence or control the judgment of the court or jury must depend upon the intelligence of the witness, as manifested by his examination, and upon his opportunities to ascertain all the circumstances that should properly affect any conclusion reached. It will also depend in part upon the degree of the mental unsoundness of the person whose condition is the subject of inquiry; for his derangement may be so total and palpable that but slight observation is

necessary to enable persons of ordinary understanding to form a reasonably accurate judgment as to his sanity or insanity. In other cases the symptoms may be of such an occult character as to require the closest scrutiny and the highest skill to detect the existence of insanity."

TRANSLATIONS.

Successful Extirpation of the Spleen.—At a recent meeting of the Society of Physicians in Vienna, Dr. V. Hecker, assistant to Professor Billroth, reported the following case. A woman, æt. 43, had, ten years previously, begun to experience pain in the left side of the abdominal region. After a lapse of three years a tumor appeared, which within the last two years had grown rapidly. The increase had been more rapid a few weeks before than at the time of the operation. It had recently become movable. In the dorsal position there was a decided projection, and a tumor the size of a child's head was felt. This tumor could be pushed to the left and turned on its axis. Its inferior and superior borders presented sharp angles. Intestinal accumulations were caused by the tumor. The liver was small. The operation showed the tumor to be a lymphosarcoma which had grown from the spleen. The connections with the mesentery and intestine were separated partly by tearing, partly with the knife, numerous ligatures being required. On account of adhesions with the pancreas, it was necessary to leave a part behind. The course of the case had been thus far favorable, and it is hoped a cure will follow.

So far, there are known to have been thirty-six cases of extirpation of the spleen: of these, twenty-one on account of leukæmia. Of the last, but one recovered.—*Wiener Med. Wochenschrift.* x.

Concerning the Behavior of Varicosities of the Pregnant after the Death of the Fœtus.—Dr. Gustave Rivet reports this case in the *Progrès Médical*, xi.: A cook, æt. 33, of good constitution, had already gone through two pregnancies, the last being an abortion at the fifth month. She complained during both her first and second pregnancies of great varicosity of the lower extremities. In the third pregnancy it again appeared during the first months. It was well developed; hard, compact cords were seen situated in the region of the ankle-joints, also on the inner surface of the left thigh. These were associated with œdema and a decided tenderness. The movements of the child suddenly ceased, the breasts became painful, and yielded some milk-drops upon pressure; the circumference of the abdomen decreased, and from that moment the varicosities began to lose in fulness and size. A few weeks later the patient gave birth to a female child, very much macerated.

The interesting facts in this case are, on the one hand, the relatively long time in which the dead fœtus remained in utero; on the other, that from the moment the death of the fœtus was known to have occurred, the varicosities began rapidly to disappear. Hence the decision is arrived at that the uterine circulation stands in a close connection with the venous, and, when it is diminished, the stasis in the veins below is reduced. x.

Inhalations in Phthisis.—From experiments with inhalations in phthisis, Dr. Renzi (*Rivista clinica e therapeutica*, August, 1884) gives the following general conclusions:

1. Inhalations of iodine and of iodoform with spirits of turpentine (one part to twenty-five, of which a few drops are placed upon a respirator) ameliorate the general nutrition, augment the inspiratory and expiratory pressure, and produce an improvement in the state of the lungs. But the fever, the diarrhœa, and the night-sweats are not modified. The cough and expectoration are especially modified by the iodoform and turpentine.

2. Inhalations of sulphuretted hydrogen and of sulphurous acid resemble each other in their effects: they increase the general strength, improve nutrition, and increase the urinary secretion. Inhalations of sulphuretted hydrogen have a special action upon respiration,—diminution of the number of respiratory movements, which become easy, tranquil, and profound,—and also upon the cough, which diminishes and may disappear. The fever, sweats, and diarrhœa are not modified.

3. Until further information is obtained upon the subject, the author considers the terebinthinate inhalations and those of sulphuretted hydrogen as occupying the first rank.—*Bulletin Gén. de Thérapeutique*, October 15.

Concerning a Special Form of Nymphæ and the Influence of the Same upon Labor.—Paul Budin (*Le Progrès Médical*, xii. 18, 347, 1884) states that in some females the labia minora unite by a prolongation posteriorly instead of terminating about the middle of the vulva. There appears then both a commissure of the labia minora and one of the labia majora. The author found this in many white females, and in one colored. In one case he found a moderately deep furrow between the two commissures. Luschka and Sinety had already described similar cases. The results of this condition are either that the child's head, when passing the vulva, is thrown forward and covered with a caul, the head being retarded by the commissure of the nymphæ, or that a rupture occurs. The latter is usually central. This is contrary to the common course of perineal rupture, in the ordinary condition of things it being usually to one side. One or both of the nymphæ may also in this case be torn loose.

The author proceeds to report at length a case of this kind, in a secundipara æt. 22. In this case the midwife, who was supporting the perineum, reported a rupture. The author examined, but found the perineum intact. A little anterior, however, he found lips of tissue of a blue color, which were hanging forward. On closer examination it was found that the left nymphæ had been torn from their insertion at the clitoris and were hanging loose from the vulva. On account of their posterior connection, the nymphæ in this patient formed a complete ring, constituting an obstacle to the advancing head. This, however, was removed through the rupture of the labia minora from their anterior attachment. Injections of a two-per-cent. solution of carbolic acid were made five or six times a day, and no evil sequel occurred. On the seventh day *post partum* the labia minora came away entirely. On the seventeenth day the genitalia were completely healed. x.

A Hair Tumor removed from the Stomach of a Young Girl through Gastrotomy (*Arch. für Klin. Chir.*, xxix. S. 609).—In a girl, æt. 15, who since her thirteenth year had been in a kyphotic condition, often complaining of stomach-trouble, there was discovered an abdominal tumor, solid and movable. It was thought to be a floating kidney, and extirpation was attempted. On opening the abdominal cavity, the tumor was found to be within the stomach, which was very pendent. An incision into this organ showed a hair tumor representing the dimensions of the stomach: weight, 281 grammes; length, 13½ centimetres; breadth, 10½ centimetres; thickness, five-sixths centimetre. The color of the hair was black on the surface, on the inner part decidedly blonde. The pieces were from one to two centimetres long. The patient had a favorable recovery from both her abdominal and gastric wounds. She explained, after her recovery, that four years previously she had for the space of one year chewed her hair energetically. The hair of the inner part of the tumor resembled quite closely her own hair. The author thought that the hair on the outer part had been colored black by preparations of iron which he had given her for chlorosis over a long period of time. This case, he said, is not without parallel. He had collected not less than seven analogous cases from the literature. In the majority of cases the chewing of the hair continued much longer, and the tumors were on this account larger. The other patients having hair tumors all died, either from uncontrollable vomiting or perforation. x.

Sudden Death after Injection of Iodine in a Case of Spina Bifida.—A little girl who had been treated for spina bifida by tapping had the lead compress removed too soon, and the swelling afterwards returned. Dr. Waltering, of Münster, aspirated the tumor, removing two tablespoonfuls of serum, and injected a half-ounce of an iodine solution (iodin. puri, 0.5, potassii iodid., 1.5, aquæ dest., 30) directly into the sac. The child suddenly stopped crying, and stopped breathing also, although the heart for a time continued to beat. The lips were livid, but became slightly better colored under artificial respiration. At the end of thirty minutes the heart had ceased to beat, and efforts at resuscitation were discontinued. The case is reported (*Allg. Med. Central Zeitung*) as a warning against injections of iodine solution into the sac in a case of spina bifida.—*Deutsche Med. Zeitung*, October 16.

EDITORIAL.

THE LESIONS OF LOCOMOTOR ATAXIA.

THE restricted view of the pathology of Duchenne's disease which regards it as a malady in which the spinal cord is invariably the site of morbid changes, and that the posterior columns, or, more correctly speaking, the posterior root-zones (columns of Burdach), and the nerve-roots, are chiefly affected, needs to be modified and slightly extended, in the light of some recent observations. Locomotor ataxia and posterior spinal sclerosis can no longer be regarded as convertible terms. A very valuable contribution was brought to the discussion of this question by Charcot (*Leçons sur les Maladies du Système nerveux*) in his classical consideration of some of the anomalies of locomotor ataxia; but quite recently several communications have appeared, which enable us to draw more definite conclusions as to the pathology of this most interesting affection. Dr. Rummo in particular has called attention* to a form in which the motor inco-ordination is entirely missing. In the case reported, the cerebral symptoms were followed, nearly two years afterwards, by neuralgic pains in the lower extremities, while the power of co-ordination of muscular movements remained perfect. Fournier last summer delivered a series of lectures on the Pre-ataxic Period of Tabes, in which he claims that the stage which precedes inco-ordination usually lasts from three to six years, but may be prolonged to thirty. He regards it as a polymorphous affection, of which the *début* may be announced in various ways: by vesical or genital disorders, and often by cerebral symptoms, which he groups under the following heads: (1) vertigo (reflex or essential); (2) various attacks (apoplectic, epileptiform, aphasic); (3) motor disorders; (4) psychic disorders; and (5) general paralysis. Without considering these (which are reviewed more fully in an interesting article, by Scribe, in *La France Médicale*, No. 102), or discussing the cases presented by M. Dejerine last year to the Paris Academy (in which no special lesion existed to account for the symptoms during life, which were found to be due in reality to parenchymatous neuritis of the cutaneous nerves), we will merely state that the conclusion of Messrs. Rummo and Fournier, that "Tabes dorsalis is an affection of the spinal cord, of the brain, and of the peripheral nerves," seems fully warranted by their observations. It would also seem that the term locomotor ataxia should yield to the word "tabes," since the ataxia of movements may be wanting during many years, and even may be entirely absent throughout the whole course of the affection. In a suggestive paper by E. C. Seguin (*Archives of Medicine*, October), some illustrations of this anomalous course of posterior spinal sclerosis are given, and the possibility is intimated of the accidental concurrence of other disorders, such as general paralysis with spinal sclerosis, any dependence between the cerebral and spinal lesion being doubtful. But he also reports a case of the extension of the pre-ataxic stage to the extraordinary period of twenty-nine years, and another in which atrophy of the optic nerve preceded the ataxic symptoms by at least four years.

* Sur un cas non-commun de tabes bulbaire primitif. Medicina Contemporanea, April, 1884, L'Union Médicale, June, and La France Médicale, September, 1884.

WE desire to direct especial attention to the gift to the German Hospital of nearly six hundred thousand dollars by John D. Lankenau, Esq., of this city, some account of which will be found on another page.

AN APPEAL TO CONGRESS.

IF to be forewarned is to be forearmed, we certainly should have nothing to fear from the advent of the cholera, which is billed to appear shortly. Sanitarians, local health boards, and the medical journals, as well as the public press, are for once agreed that the presence of epidemic cholera in this country may be expected within a few months.

The American Public Health Association at its last meeting, and the recent conference of State Boards of Health, gave serious consideration to this subject, and adopted certain valuable recommendations for the prevention of the epidemic, which have been printed in the form of a report and widely circulated. The essential factors to the prevalence of cholera in this country in epidemic form are, first, its importation by ships from infected ports, and especially from India; secondly, local disregard of hygienic principles; and, thirdly, the transportation of the poison by patients in clothing or about their persons in going from place to place while suffering from some stage of the disease. To combat these three factors needs the practical co-operation of international, national, and local health boards.

In view of the threatened introduction of cholera into this country during the coming year and the consequent waste of life and property and derangement of commerce, trade, and productive industries, the conference, besides warning local health boards to increased vigilance, declared that "the general government should maintain such a national health service as shall, by rigid inspection at the port of embarkation, question the freedom from disease and infection of all persons and things from infected districts, and shall secure the surveillance of such persons and things while on shipboard, and, when necessary, detention at quarantine stations on this side for treatment and disinfection." The conference urged upon Congress the establishment of such a service by attaching to the foreign consular service medical officers of health, to be either accredited consuls or attached to the consulates, charged with the execution of the above duty.

It is peculiarly unfortunate that the inspection and quarantine service inaugurated by the National Board of Health is now inoperative for want of appropriation by Congress. It is to be hoped that the members of the next Congress will have their attention so strongly directed to the necessity of prompt action in this matter as to lead them to act upon it early in the session and make the necessary appropriation required to establish an efficient national protective sanitary service.

While local health boards can do very much towards restricting the spread of the disease and reducing its mortality, yet they are almost powerless with regard to preventing its introduction. The National Board of Health must do this work, or it will be left undone.

THE NEW YORK STATE MEDICAL ASSOCIATION.

THE first annual meeting of the New York State Medical Association, which was held at the Murray Hill Hotel, New York, on November 18 and the three following days, demonstrated very conclusively the strength of the revolt from the arbitrary action of the old State Society upon the Code question, three years ago. While many of the members of the new organization might have been in favor of the objects aimed at by the committee in its report, they believed that the step proposed was injudicious and hasty, and calculated to create a division between physicians of New York and those of other portions of the country. That step was taken, and, as had been anticipated, the American Medical Association at St. Paul refused to receive the delegates from the

New York State Society. The establishment of a new State Association and of a second County Medical Society in New York City was almost a natural result of this state of things; and now, looking at the success of the meeting of the new Society, at the value and number of the scientific papers that were read, the well-sustained discussions, and the standing of those who participated, we are almost tempted to rejoice at the division in the profession which stimulated to such activity and brought out such good work. The founders of the new Association deserve to be congratulated upon its success. Owing to pressure of Society reports, we shall not attempt an analysis of the numerous papers read at this session, as we learn that the *New York Medical Journal* has arranged to publish the official report of the proceedings. The list of officers elected for the ensuing year is as follows:

President.—Dr. John P. Gray, of Oneida County.

Vice-Presidents.—Second District, Dr. W. H. Robb, of Montgomery County; Third District, Dr. J. G. Orton, of Broome County; Fourth District, Dr. Joseph O. Greene, of Erie County; Fifth District, Dr. J. C. Hutchinson, of Kings County.

New Members of Council.—First District, Dr. William Gillis, of Franklin County; Second District, Dr. R. C. McEwen, of Saratoga County; Third District, Dr. Frederick Hyde, of Cortland County; Fourth District, Dr. Darwin Colvin, of Wayne County; Fifth District, Dr. J. W. S. Gouley, of New York County.

CARBOLIC ACID IN THE TREATMENT OF INTERMITTENT FEVER.—Dr. Dieulafoy, in a case of obstinate ague which had recurred in spite of large doses of quinine, tried hypodermic injections of phenic acid in one-per-cent. solution, .025 gramme (gr. $\frac{1}{3}$) being given night and morning for two weeks, when the chills were finally arrested. Three days later the injections were discontinued and the patient discharged cured.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THERE has recently occurred a rather lively episode in a side-wing of the medical world here. Since the Radical section of politicians has become a distinct factor in the Liberal ranks, and their voices have been heard in Liberal ministries, the education of the people has been distinctly kept in view. The Chartists were true to themselves in deciding that if every man ought to have a vote in the election of the legislators, it is well to educate him so that he may be fit to use it properly. Consequently, some ten years ago the School Board came into force,—otherwise compulsory education,—the rates being used to furnish the necessary outlay in proper school-rooms, etc. Now, of course, the argument that the brains of our children are the finest raw product of our country, and that England has obtained her position in the world by manufacturing raw products, and therefore the children must be educated, is sound enough. But, unfortunately, there is no such thing as unalloyed good in this imperfect world; and, laudable as this project is in principle, there have been found some drawbacks in the working. The London School Board has taken a decided step in the selection of the elementary books by which the children are to be taught, and the good effects of their judgment are to be seen in the array of school-books now issuing from the press, in every way a marked improvement upon, as well as contrast with, those of a period but little anterior to this movement. Everything is made as easy for the children as possible, but the encouragement given to the teachers to push them through the different standards, by making the additional salary to be won dependent upon the percentage of passes, has told upon the children unfavorably as regards their physical health. It is all very well to push on children who come to school with a full stomach and a well-fed brain, but when the belly is empty the brain flags; consequently, the excessive pressure, especially upon little half-fed town mites, has begun to tell in obvious effects.

Mr. Mundella, the head of the education department, is an advanced Liberal, and was originally a Chartist when young. A dispute arose first between him and Dr. Rabagliati, of Bradford, Yorkshire, who charged the School Board with overworking the children. As the dispute grew warmer, Dr. Crichton Browne, the Lord Chancellor's Visitor in Lunacy, was drawn into it. Perhaps Dr. Crichton Browne's name may not be unfamiliar to the readers of these letters (if such there are), but a few words about him may not be out of place. He first became con-

spicuous as the Medical Superintendent of the West Riding Asylum at Wakefield, where he not only administered the asylum in a manner to elicit the warmest admiration of all, but he started what was practically a school of psychological medicine. He fired his subordinates with his own enthusiasm. Careful clinical observations were followed by close examination of the bodies, as well as the brains, of those patients who died. The West Riding Asylum Reports were the most advanced works bearing upon insanity of their day. All of which testifies that there is a practical side to Dr. Browne's intellectual brilliancy. Such a man was not likely to make a mistake if he knew it; and he was not likely to make any mistake when he was asked to investigate the matter of overpressure in elementary schools, and agreed to do so, albeit the demands upon his time were already very great. He made his observations, and after that his report, which so far substantiated the fact that overpressure did exist that it was not allowed to see daylight without an appendix or rider attached to it from an official of the education department, named Mr. Fitch, explaining away much of it. The two were published together, whereupon a storm began to blow.

Dr. Crichton Browne has an unusually large vocabulary, and writes and speaks with a fluency and flow of language which is very unusual. Consequently, some newspapers talked of his rhetoric, and insinuated that this took the place of facts, or, rather, perhaps, that meagre facts were decked out in ornate language till they looked larger than they actually were,—a very unfair assumption, as Dr. Browne only used his ordinary language. He, of course, was not a man to be shut up or have his mouth closed in any such violent manner, and, in a series of letters in the *Times*, has thoroughly vindicated himself from the charges levelled at him. In this "policy of reprisals" the unfortunate official has been sat upon effectually, and has been taught a lesson which ought to be useful to others. At a recent meeting of the teachers of the Metropolitan Board Schools a motion approving of Dr. Browne's report was carried unanimously.

It is a great pity so much warfare has been occasioned, but it has had the effect of demonstrating that, however admirable education may be, there are limits within which it is well to keep, and that the brains of famished little children are easily overtaxed, and therefore that their tasks must be proportioned to their powers. Especially are home-lessons to be deprecated for poor little waifs that have no privacy for study. The whole controversy will bear fruitful results in time.

Of course the education department were disposed to treat Dr. Crichton Browne in that cavalier manner which has of late been the fashion towards the medical profession; but it made a mistake. If we had a few more men like Dr. Crichton Browne in our ranks it would be a most fortunate thing for the profession in every way. His spirited conduct will, perhaps, inspire others of our profession to kick back when assailed; and, further, such handling of a public department may teach officials to conduct themselves respectfully towards the framers of reports upon disputed matters, especially when these latter are invited to take upon themselves troublesome inquiries, as Dr. Browne was in this case. It would seem that human nature is human nature, and, whether a government consists of the representatives of the "few" or the "many," it has a tendency to be high-handed.

As a perfect contrast to Dr. Browne's ways and theory of life, may be mentioned a small storm in a teapot which blew recently betwixt a well-known member of the profession—more before the public some years ago than at the present time—and a not unknown member of the profession, who, however, does not hold a place in the first rank. The latter, some time ago, wrote a book on a subject upon which the former was a well-known writer some twenty or five-and-twenty years ago. On its appearance the ex-author wrote the author a letter of congratulation upon the work, and expressed a hope that before long some opportunity would be afforded him of teaching his views to students. In his advertisements of his book the author made use of this letter,—perhaps rather sharp practice, as the letter was evidently merely a private one. After the lapse of some time the advertisement was brought under the notice of the writer of the letter, who thereupon sat down and wrote a second letter indignantly protesting that he had never even seen the book. Of course this was a little too much for the author, who, having kept the first letter, sent it on for the writer's inspection. He admitted it was no forgery, but could not throw any light upon the discrepancies betwixt his two letters. Now, this curious letter-writer is a man who occupies a high position in his college, and in so far ought to tread warily and set an example. His conduct is that of too many who creep into conspicuous positions,—viz., a mixture of insincerity and professing righteousness, which does not always succeed.

The natural interpretation of the two contradictory letters is not far to seek, and is probably this: On noticing the book (being an authority on the subject), he writes to the author a fulsome letter, evidently not the outcome of careful study of the work (for he does not even remember it), but in order to impress himself upon the writer, who lives out of London, and who might have patients coming up to town, which patients might wish to know whom to consult when there. The *tout ensemble* of the thing looks most

suspicious. And when the flattered author makes another use of the letter to what its writer expected,—viz., employs it for advertising purposes,—the writer gets up some virtuous indignation and writes another letter of totally opposite character. In this instance the schemer fell into his own trap in a manner utterly unexpected. It is a trifle, but it reveals a depth of depravity that is certainly not assuring at a time when the medical profession is writhing in the agonies of all-round snubbings, when the Medical Amendment Bill has been twice rejected by Parliament, when the medical press has been using forcible language to the Corporations, and even when the conduct of the General Medical Council has been the subject of some strong animadversions. Self-respect leads to the respect of others; and our profession at present seems only too strongly inclined to give the enemy opportunities of which it avails itself, to the detriment of the profession and the regret of those of it who see clearly what the real position of affairs is, and how small are our prospects of raising it if leading members of the profession act as the writer of the letters just referred to has done. It is piteous to see men of position dropping themselves by their own deeds and doings into such very questionable positions, from which a little self-respect would save them. It is the old story over again. When Moses tarried on Mount Sinai for the tablets containing the Decalogue, Aaron in the mean time gathered the gold of the tribes and made a molten calf, and the people worshipped, crying, "Here be thy gods, O Israel, which brought thee up out of the land of Egypt!" So it was then, and so it is now. And the worshippers of the golden calf are after idolatry yet! We certainly do seem in need of some other gods than those in vogue at present.

Those of the inhabitants of the United States who feel an interest in forthcoming generations will read with a sense of instruction a small work on "Dental Caries" just issued by Henry Sewill, a well-known dentist here. It is not so much the pathological relations of the wide-spread evil, but its causal relations, which will attract their attention. Mr. Sewill holds that as civilization progresses the jaw lessens, and then the teeth are imperfectly developed, and, consequently, from cracks or pits in the enamel of these teeth the immediate causes of caries make their way into the tooth, and so work its ruin. As the teeth of the inhabitants of the United States are notoriously in a bad way, it may be well for those intending to marry to know that "crowding and irregularity of the teeth are mostly caused by smallness and malformation of the maxillæ,—a condition which is, no doubt, largely associated with the physical type presented by highly-civilized man." Consequently, "sexual selection" is a great force in action. "The type of female beauty for many ages has included a small, delicate jaw, the heavy jaw, or anything approaching to prognathism, being universally deemed a disfigurement." However desirable, from the point of view of tooth-development, it might be to select a spouse of the "mickle-mouthed Meg" type, who so exercised the mind of one of the ancestors of Sir Walter Scott, it is scarcely to be expected that a man will marry for the sake of the teeth of his grandchildren. Mr. Sewill, indeed, seems to see this, for he adds, pathetically, "I am afraid we cannot hope that, for the sake of the teeth of posterity, men will be advised to pick out big-jawed wives; but we can, at least, seriously impress hygienists with the fact that the human jaw, for its due development, needs adequate use, and that no dietary, however otherwise suitable its constituents, can be perfect which is composed of uniformly bland and soft substances calling for little or no mastication." And then he falls foul of the French cook, as follows: "The French use their jaws less than any other nation; they are the best cooks in the world, and the whole population, without exception, lives upon the softest food, including bread of the most delicate manufacture."

Having thus laid a ban upon "beauty's bewitchment" with a delicate chin in the choice of a wife, and pointed the finger of scorn at the French cook, it is a relief to find that he feels no animosity or rancor towards the schoolmaster. "It has been plausibly argued that dental deterioration—and especially progressive deterioration—may be accounted for by the overwhelming demands upon the vital powers by the growth of the brain and its increased exercise in modern life. The brain and the jaws are alike fed from the common carotid artery, and, it is urged, the demand for blood by the growing and working brain leads to imperfect supply of the masticatory organs. This argument gains support from the fact that the people of the United States, with certainly the worst teeth, present a type of humanity one of whose most striking characteristics is enormous activity of brain and nervous system, with expenditure of vital energy through these channels. But I believe that we shall find this hypothesis will not work, and it remains hypothesis, difficult of negation, impossible of proof." Just think what a long sigh of relief the founders of general education in New England must draw at this expression of opinion,—that is, if disembodied spirits possess inspiration. Perhaps those beings in "astral forms" (*à la* Madame Blavatsky) will kindly convey Mr. Sewill's opinions to the shades of these Puritan worthies as a work of human charity!

In case any spirited American citizen, fired by Mr. Sewill's remarks, wishes to sacrifice himself and his tastes in order to secure a perfect set of teeth for his descendants, the

writer could recommend to his attention the "Earthmen" (and women) from the Kalahari Desert, in South Africa, now on show at the Aquarium, Westminster. They are the most complete savages on the globe (unless it be that lowly tribe living in California, the Digger Indians"); but they present ideally perfect teeth to the eye of the observer,—teeth the enamel of which is perfect, without flaw through which acids and bacteria could penetrate into the interior. How far, however, against this tooth-perfection may weigh sundry drawbacks it is impossible to say. Their women do not seem calculated to form intellectual companions for civilized men; and though the jaws which carry these perfect teeth are not remarkably prognathous, still the face is not attractive, nor its expression very *spirituelle*. If, however, in his new-born enthusiasm he is willing to cast aside everything as compared to dental perfection, he could find a bride to his mind among these human vipers,—for little yellow brutes with poisoned arrows are these "Earthmen."

What Mr. Sewill does regard as a great cause of that imperfect development of enamel which predisposes to caries the reader must seek in the book itself, which is replete with information of much practical value. If the reader is not equal to the self-denial of espousing a big-jawed savage, it may be no breach of confidence to tell him what Mr. Sewill thinks it well to avoid in a wife: "This is the type most frequently found in females in which there is often, with a fragile form, considerable facial beauty; in which the eyes are large and expressive, the complexion fair, with the blue veins visible beneath the skin. This is the not uncommon type which, without further description, will be recognized, and in which I have invariably found the teeth, although well shaped and often uncommonly white and beautiful to look at, covered with the softest and most defective enamel."

Really, what betwixt Dr. Crichton Browne and Mr. Henry Sewill,—too much education and perverted ideas of beauty,—civilization seems to be progressing too fast for the physique of the future.

J. Milner Fothergill.

CHICAGO.

SINCE my last letter the new Presbyterian Hospital has been formally opened and patients admitted. The building, though not large, is well appointed, and possesses all the modern and most approved conveniences, ventilation and heating being so arranged as to give the best results. The beds, as soon as ready, have been quickly occupied, and at this time everything about the hospital is moving smoothly and satisfactorily. The interest of Rush Medical College in this institution was transferred to the Presbyterian Board, with the understanding that the trustees of Rush should appoint the medical and surgical staff. This has been done in as impartial a manner as possible, but not without some dissatisfaction to the other medical schools of our city. Some of the positions were tendered to members of the several faculties of our schools, but were declined by the gentlemen to whom they were offered, on the plea of not having necessary time for the proper administration of the duties; others stating that the hospital was at an inconvenient distance, etc. The result is that the new hospital has been styled a "mere appendix to Rush Medical College."

The facts are that the staff is a good one, and, though strongly represented by Rush, no fair-minded observer can offer reasonable objection, in view of Rush Medical College having transferred to the Presbyterian Board all interest (not by any means insignificant) in the property, and all control other than appointment of staff for service.

Our County Asylum for the Insane is now the scene of great contention and not a little disordered investigation. For many years this institution has been the prey of political hangers-on, the different offices being too often filled by persons wholly incompetent,—each official enjoying a sinecure, delegating his duties to subordinates or patients. In addition, there seems to have been systematic misdirection of the charity,—funds finding a resting-place in the pockets of interested leeches, and patients left without necessary care and bodily comforts. A few months ago Dr. Spray retired from the superintendency, and was succeeded by Dr. J. G. Kiernan, who at once joined hands with Dr. S. V. Clevenger in an effort to bring about needed reform in the administration of the general affairs and the treatment of the patients.

These gentlemen found six hundred and fifty people huddled together in quarters barely sufficient to accommodate three hundred. This condition could only be partially ameliorated, and Drs. Kiernan and Clevenger addressed themselves to the correction of the most flagrant abuses, and in so doing excited the wrath of the County Board. For a time there was a war of words, and then came positive action on the part of the superintendent. Inefficient subordinates were discharged, and their places filled by persons selected by Dr. Kiernan without reference to the wishes of the politicians.

This was followed by a bitter controversy with the former superintendent, resulting in threats of violence against Dr. Clevenger, the pathologist.

In a short time Dr. Clevenger succeeded in interesting the Citizens' Association in the affairs of the institution, and an investigation was commenced. He has, in addition, sent copies of a printed letter to the members of

the County Board, reciting that the employés are in a state of rebellion against the superintendent, and that the medical officers will be compelled to resign unless they take some action. At the last meeting of the Chicago Medical Society the case was again stated by Dr. Clevenger, and a committee of professional men was appointed to act with laymen in an examination of the charges preferred by the officers of the asylum.

While the abuses are beyond question, the means for their correction have not been well directed, because of the too personal character of the controversy. The same thing might be said of more than one of our State institutions; but it is not likely to be said as long as the present political qualification system prevails.

Scarlet fever is quite prevalent, and in this connection it is quite interesting to observe how many householders and others avoid open display of the red card. By a little persuasion, the visiting health officer nails the caution-card upon an inside door, often back at the end of a dark hall, where it cannot be seen. This practice is most common in large boarding-houses, where it is the more reprehensible as it assists in the spread of the disease by begetting a false sense of security.

Diphtheria is beginning to attract attention, and fears are expressed that it is likely to become wide-spread.

Our medical schools have entered the fall term with increased numbers over those of last year, and the graduating classes will be larger than ever before. M.

November 18, 1884.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THE Semi-Annual Conversational Meeting of the Society was held October 23, 1884, the President, E. O. SHAKESPEARE, M.D., in the chair.

Dr. FRANCIS DELAFIELD, of New York, by invitation, read a paper on

*The pathology of broncho-pneumonia.**

Dr. PEPPER said he had listened with very unusual interest to the paper of Dr. Delafield, in which he had so distinctly and concisely set forth his views on this very common disease.

He thought that all who had listened to Dr. Delafield would agree with him in congratulating the author upon the clearness and force with which he had described a condition which had hitherto often been confused by prolix description and by want of definiteness in separating different anatomical conditions. In regard to the term "broncho-pneumonia," which Dr. Delafield prefers, he has proved by his anatomical studies of the infiltration of the bronchial walls and of the surrounding parenchyma, that this term is strictly applicable to the cases upon which this paper is based.

Dr. Pepper stated, however, that, though chiefly from a clinical stand-point, he was inclined to prefer the term catarrhal pneumonia, as probably including the form described by Dr. Delafield, as well as certain other forms which seem to him to be necessarily included in a complete picture of the disease.

For instance, there are many cases in adults which begin with rigor, followed by high fever, with temperature of 102½° to 104° F., with cough hard and dry at first, and later with muco-purulent expectoration, with no very definite physical signs. Careful examination will show local impairment of resonance, coarse crackling râles on deep inspiration, and weak vesicular murmur. This condition may be limited to the apex or to the neighborhood of the root of one lung, or may occur elsewhere. The cases have a duration of from eight to twelve days, and terminate by lysis with resolution, though not rarely some cough remains, and the lung is sensitive and prone to recurring attacks, which in subjects predisposed to phthisis may induce that disease.

It seems to him difficult to regard these cases as anything else than mild catarrhal pneumonia; for this type of pneumonia agrees with other catarrhal affections in the wide range of severity presented by different cases. On the other hand, there are cases, much more common in children, in which disease extends from the bronchial tubes into the lobules to which they lead.

The commonly-accepted opinion that the lining of the alveoli and air-vesicles is susceptible to catarrhal inflammation, appears to me well established. In such cases the disease may extend outward to the peribronchial tissue, as emphasized by Dr. Delafield, and lead to secondary interstitial changes, and also, in consequence of obstruction of bronchi, atelectasis occur; the aspiration of irritating bronchial products may fill some of the alveoli, or finally they may become impacted with the results of catarrhal inflammation of their walls. Subsequently, caseation with softening may give rise to small abscesses with breaking down of the walls of the air-vessels, or with perforation of the pleura, or inspissation may occur with reabsorption of infectious material, with the development of general tuberculosis.

It did not seem necessary to dwell upon the cases in which atelectasis occurred as a primary condition with the subsequent development of pneumonic centres.

It seems to him impossible to consider ca-

* See page 153.

tarrhal pneumonia without taking the comprehensive view which would include all the varieties above indicated; though the term "broncho-pneumonia" as used by Dr. Delafield might be most appropriate to the special conditions described by him.

Allusion was made to the very interesting physical signs attending the course of atelectasis in the course of catarrhal pneumonia of children or of adults, where considerable areas of the lung, or even an entire lung, might pass into this state, to be followed before long by the re-establishment of respiration and the disappearance of the physical signs. Difficult questions of differential diagnosis may present themselves, requiring critical examination. From an allusion made by Dr. Delafield, it appeared that he regarded lobar pneumonia as being, like broncho-pneumonia, induced by the ordinary causes of idiopathic inflammation. The argument, which did not favor the view that all lobar pneumonia is a specific constitutional disease, or is dependent upon a special microbe, did not appear to be conclusive, and he was glad to know, from the remarks of Dr. Delafield, that he holds the same view.

Dr. BRUEN said he rose to call attention to the observations of Hamilton, of Aberdeen, in reference to the peculiar basement-membrane of the bronchial tubes, which determines the chronicity of bronchitis, and probably the interstitial changes in chronic broncho-pneumonia. Hamilton, in speaking of the denseness of this basement-membrane, gives it the importance of a fascia, which determines the direction in which the inflammatory products of bronchitis shall be absorbed,—viz., by the lymphatics rather than by free exudation into the bronchial lumen. The interlobular connective tissues are permeated with fibrous bands, which radiate from the fibrous coat of the bronchi towards the pleural surface. Dr. Bruen thought that, if careful study of the lymphatics were made, the absorbed products of an acute or subacute inflammation could be traced throughout the lung, finally leading to enlargement of the bronchial glands.

The importance of the basement-membrane is further illustrated by the phenomena of pneumonikoniosis and anthracosis. Immediate absorption from the bronchial tubes does not occur, although the tubes are always exposed to carbonaceous matter, as evinced by the blackened sputa, yet the tubes are unpigmented, the carbonaceous or organic dust being carried down into the alveoli, whence it is absorbed, and the whole parenchyma of the lungs and the bronchial glands are blackened, but always strictly in the course of the lymphatics.

In children of a strumous habit, forms of bronchitis of an obscure nature often occur. Congested areas near the root of the lung are recognizable; abundant mucous râles and frequently laryngeal spasm at intervals form an important symptom. These symptoms are often referable to enlargement of the bronchial glands, and the nervous symptoms are due to irritation of the pneumogastric nerves.

Dr. J. C. WILSON asked whether Dr. Delafield designed to describe one variety of a group of affections to which the terms broncho-pneumonia, catarrhal pneumonia, desquamative pneumonia, etc., are somewhat vaguely and interchangeably applied, or to include the whole group in his account, and under the designation of broncho-pneumonia. If Dr. Wilson had understood the paper aright, he thought it certainly had referred to an especial variety of the affection in question, for there are encountered cases which differ both clinically and anatomically from the disease described by Dr. Delafield, and in which the lesions spread not only in a direction internally, from the affected bronchial tubes to the peribronchial structures, but also in the direction of the long axis of the tubes to involve the terminal (subpleural) vesicles, and this, according to widely-accepted views, often without antecedent atelectasis.

Dr. CARPENTER said that he had very little, indeed, to give of value in a pathological discussion, but would say, at the same time, that after thirty years' experience he had arrived at certain conclusions, not perhaps new, but which had been gathered in one set of cases, —viz., anthracosis. They are a very striking set of cases. They all originate in a bronchitis, which differs from the ordinary form of that disorder in one very striking symptom,—viz., great oppression of breathing. This oppression is far greater than can be accounted for by ordinary bronchial inflammation. It depends on interstitial disease or peribronchitis. A true broncho-pneumonia is set up, the cause being a special one,—viz., inhalation of coal-dust. In these cases so great obstruction to the circulation is caused by the interstitial exudation that the circulation is very seriously embarrassed. The heart suffers, dilatation, or hypertrophy with dilatation, is produced, and a form of dyspnœa, known as miner's asthma, occurs. These cases are essentially chronic ones. He had only the day before seen a patient die with this disease who had been under his care for several years, and in whom no lesions but those of peribronchitis could be detected.

Many of these cases, however, in a chronic progress, do develop all the symptoms of phthisis. Slow alterations of structure occur, cavities form, and all the pathological conditions of the so-called fibroid phthisis are found on post-mortem examination. He therefore claimed that these cases are entitled to constitute a special form of broncho-pneumonia. He agreed with Dr. Pepper that acute or subacute broncho-pneumonia left sensitive areas, leading often to subsequent phthisis. In his observation, fibroid phthisis was not a true tuberculosis, but a chronic de-

generation of lung-tissue, due to a pre-existing broncho-pneumonia, such as he had observed in anthracosis.

Dr. OSLER said that his experience in many points tallied with that of Prof. Delafield. In the broncho-pneumonia of adults the pneumonic process, he believed, most usually spreads from the bronchi. He referred also to those cases of broncho-pneumonia which followed brain-injury, or disease affecting the pneumogastric centres. In such cases the disease was deeply seated, and we find that the morbid process often surrounds the bronchi but does not involve the terminal alveoli. The reverse is true in the case of children, in whom the disease is more peripheral, is nearer, and may be just beneath, the pleura. He was glad that Dr. Carpenter had raised the point as to anthracosis. Dr. Osler had been able to examine several cases of this affection in its very early stages, and could testify that it begins in the bronchi and thence extends to the peribronchial tissues. It is primarily then a broncho-pneumonia, and in every case he had found small disseminated black lumps resulting from localized broncho-pneumonia, which, by their fusion and extension, produce a form of fibroid phthisis.

Dr. TYSON had little to add to what had already been said. He had, however, first expressed his gratification at the simple clearness with which Dr. Delafield had presented the question. Dr. Tyson had been very much impressed with the diversity of nomenclature of the disease under consideration, and it would be usful if we could agree upon some common term. For a long time desquamative pneumonia had seemed to him to be the best term, but from a study of the pathological histology he thought the term peribronchial pneumonia more suitable. If now the adjective desquamative be added, we have a term which will be still more comprehensive and exact.

Dr. Tyson thought that our understanding of the enormous peribronchial cellular infiltration would be much simplified if we lose sight altogether of the idea that there is essentially any form of inflammation except interstitial inflammation. He had come to the conclusion that there is no such thing as catarrhal or parenchymatous inflammation, the phenomena usually considered characteristic of these being secondary. The wandering out and massing of leucocytes is the one essential factor of the inflammatory process. He would like to ask Dr. Delafield where he would draw the line between this process and tubercular phthisis. He presumed that Dr. Delafield agreed with all other observers in admitting that broncho-pneumonia does sometimes terminate in tubercular phthisis, and when this occurs it is often difficult to say where the broncho-pneumonia ends and where the phthisis begins, although the extremes may be easy of recognition.

*

Dr. FORMAD would like to ask the lecturer's instruction how to distinguish broncho-pneumonia in its *chronic* form from *tubercular* broncho-pneumonia. Like Dr. Tyson, he felt that he was unable to draw a line of distinction between the two affections. Indeed, he had been unaware of a non-tubercular form of broncho-pneumonia in man until he saw Dr. Delafield's excellent records and representations of this lesion; this being explained by the fact that he had dealt almost entirely with the dead, while most of the speakers had shown that, although broncho-pneumonia in its *acute* form was a common disease, it did not prove fatal in the vast majority of cases, the patients either getting well or the disease assuming a chronic course.

Dr. Formad fully recognized *acute* broncho-pneumonia as an independent affection, although he believed to have observed this lesion post mortem only in dogs, such as induced artificially by means of forced inhalations of a spray containing irritating particles. Dogs with such artificial broncho-pneumonia (even if tuberculous sputum was resorted to to induce it) Dr. Formad had observed always to recover within a couple of months; but if the dogs were killed before the end of the first month after the operation the post-mortem showed invariably an acute broncho-pneumonia not distinguishable from that described by Dr. Delafield as occurring in man. Throughout the lung-substance are seen small nodes of irregular outlines in size resembling tubercles.

Under the microscope these nodules show to consist of mere unorganized collection of cells, often in a state of retrograde change and mixed with mucus and débris; this exudate being limited to the lumina of the bronchials and their pertaining groups of air-vesicles (the acini) which they fill. On section these artificial boundaries give rise to the appearance of nodes. Very often epithelial cells and mucus from the bronchi have been seen intermingled with the purulent contents within the air-vesicles; this suggests that the exudate contained in the latter may have been partly aspired from the bronchi (during forced breathing) and was lodged in the air-vesicles as foreign material.

These lesions have been mistaken by stupid observers for true tubercles. *Acute* broncho-pneumonia in man appears to be a lesion perfectly analogous to the one described above in dogs. The human disease once becoming chronic, its distinction from tuberculous broncho-pneumonia ceases.

Dr. DELAFIELD, in closing the debate, said that all the speakers had brought out what was one of the most difficult points concerning broncho-pneumonia, namely, its limitations. Strictly speaking, every pneumonia is a broncho-pneumonia, and the application of the term to a certain group of cases is of course arbitrary. He believed, however, that the

name is most properly employed to designate the group of cases which he had described.

In anthracosis there is a chronic bronchitis and also a chronic pneumonia, but yet the lesion is not, properly speaking, a broncho-pneumonia.

He did not believe that the inflammation travelled directly from the bronchi to the air-vesicles into which they entered, but that the appearances which simulated this were due to atelectasis.

He thought that the term catarrhal pneumonia was a very bad one, and that the air-vesicles were structures entirely different from mucous membranes.

He did not believe that broncho-pneumonia was a form of phthisis or led to phthisis, but that phthisis had its own special anatomy from the very beginning.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, NOVEMBER 6, 1884.

The President, R. A. CLEEMANN, M.D., in the chair.

REMOVAL OF UTERINE APPENDAGES FOR MENSTRUAL EPILEPSY—RECOVERY.

DR. E. E. MONTGOMERY exhibited the specimens and read the history of the case. Sarah H., æt. 17 years, was admitted into the Philadelphia Hospital April 1, 1884. She suffered from an attack of inflammatory rheumatism in childhood, and began to have epileptic seizures in her thirteenth year. These were slight at first, but have recurred every month, increasing in number and violence, so that at present she is unconscious from ten days to two weeks out of each month. There has only once been a trace of menstrual discharge, and that for a single day only. There is no history of any chronic disease in the family: brothers and sisters are healthy. The patient was pale, flabby, anæmic, poorly developed, and extremely nervous. The external genitals were but slightly developed, the uterus small, and no special tenderness over the pelvis. Iron, tonics, and a generous diet were given; the bromides were not well borne. Owing to her youth and the fact that she had not yet menstruated, it was deemed best to undertake to establish the menstrual function and exhaust the antispasmodics before resorting to operative interference. The failure of all remedial measures was complete, and on September 13 the operation was performed; both ovaries and tubes were removed. No antiseptic was used about the wound. All the water used had been well boiled. Absorbent cotton was placed over the wound, which had been closed with silk sutures. The operation occupied thirty-five minutes. The recovery was uninterrupted until the night of the 26th of September, when she had four epileptic seizures. There were recurrences of slighter attacks during the next three nights, but they were shorter, and during the intervals she was perfectly conscious. During the first four days of October, spells of staring, with momentary unconsciousness, occurred, becoming less frequent and lighter. A well-marked convulsion on the night of October 14 was followed by from one to four convulsions daily until the 29th. But they have not been so severe as before the operation.

REMOVAL OF PAROVARIAN CYST—RECOVERY.

Dr. E. E. MONTGOMERY presented the specimens and related the history, as follows: Mrs. A., æt. 30 years, native of England, married, never pregnant, has suffered from an enlargement of the abdomen for seven years. As it was first noticed a few months after her marriage, she supposed herself pregnant. Her menses have never been interrupted, now occur every three weeks, are very slight, and have never been excessive. She suffers from severe pain the week before menstruation over the lower portion of the abdomen and through the hips. She suffers at other times from pain in the feet and legs and from a sensation of weight. The tumor has been tapped some six times; the fluid was always of a pale straw color. The largest quantity removed at any one time was forty pounds. Previous to its removal her weight was one hundred and two pounds. The last tapping was on June 27, 1884. She has had four attacks of peritonitis.

When first seen, last July, two weeks after the last tapping, the abdomen was swollen and tender to pressure; fluctuation was distinct. Since that time the abdomen has increased considerably in size, presenting a prominent tumor, distending the whole abdomen, nearly symmetrical, but projecting slightly to the right side. Circumference at umbilicus, thirty-two inches; distance from symphysis to umbilicus, seven inches; to ensiform, thirteen inches. Fluctuation distinct over the whole tumor. Coughing projects the whole mass forward and downward. Her general condition is good; she is quite active.

Diagnosis.—A parovarian cyst.

Plan of Operation.—Exploratory incision, remove the tumor if possible; but, if the adhesions were too great to permit that, then to open the sac, stitch it to the integument, and introduce a drainage-tube, and thus secure obliteration of the sac.

Operation.—October 9. Abdominal wound four inches; adhesions universal, but generally broken up without difficulty; no ligatures were needed. The intestines were not seen, being concealed by old inflammatory

deposits. The right ovary was enlarged, and was also removed. The wound was closed with seven sutures, and a glass drainage-tube introduced. Salicylated cotton in a thick layer was placed over the wound. Suppositories of morphia were used to control pain, which continued to a greater or less extent for two weeks, arising partly from inflammatory conditions and partly from collections of gas in the intestines. The abdominal wound discharged freely, three ounces the first day. The drainage-tube was removed on the 13th, four days after the operation, but the discharge of bloody serum, pus, and flaky lymph continued for full two weeks later, when the wound closed entirely and the patient was discharged.

Dr. B. F. BAER presented the specimens and read the following report of a case of

PLACENTAL POLYPUS WHICH SIMULATED MALIGNANT DISEASE OF THE UTERUS.

The patient was 35 years of age, married, and had two children at full term, the last twelve years ago. She has had several abortions since, but otherwise she has enjoyed good health. Her mother died at the age of thirty-eight, of cancer of the uterus. In the early months of this year our patient first noticed that her catamenia were becoming too frequent and were attended with expulsive pains and a fetid, watery discharge in the intervals. The blood-loss increased in quantity, and she soon began to show signs of failing health in pallor and loss of flesh. She would not permit a physical exploration until the latter part of July, when she had a violent flooding, with great pain.

Examination now revealed to Dr. R. Armstrong, of Lock Haven, Pa., whose patient she was, a healthy condition of the cervix and a normal os, but the body of the uterus was enlarged to more than double its natural dimensions; it seemed to be symmetrical and rather softer than usual. The hemorrhage was controlled by ergot and rest. Although the grumous fetid discharge and the uterine tenesmus continued, she did not have another severe attack of metrorrhagia, probably because of her exsanguine condition and the fact that she was suffering from septic absorption. Her temperature rising as high as 104° in the afternoon, she had distinct rigors. Her abdomen was tympanitic and very tender to the touch. The physical condition of the uterus led the doctor to introduce two tents into the cervical canal on September 23. They were allowed to remain twenty-four hours, although their presence increased the violence of the symptoms. When the tents were removed, a rather soft, friable mass could be felt presenting at the internal os. This led to a fear that the disease might prove to be malignant. A severe colliquative diarrhœa now set in, and the patient's strength became so much reduced that nothing could be done except to administer remedies to check the diarrhœa and prevent collapse.

On the morning of the 25th, through the kindness of Dr. Armstrong, I saw the patient. Temperature 103°, pulse rapid and weak. Stomach irritable, rejecting everything taken, bowels still quite relaxed. Her face presented the ashy hue of malignant disease. The outlook was not favorable for an operation, which would necessitate the dilatation of the cervix sufficiently to remove the diseased tissue, which evidently occupied the uterine cavity, but it was the only course to pursue.

Ether was administered. The uterus was found retroverted and adherent to the floor of Douglas's cul-de-sac. The cervix was rigid and but slightly patulous. In view of the existing peritonitis, we concluded that it was best that I should endeavor to remove the contents of the uterus without a further attempt at dilatation, fearing rupture of adhesions and increased inflammatory action. I passed the wire loop of the écraseur through the os, and by careful manipulation luckily succeeded in getting it over the tumor and up to its attachment. Drawing upon the wire, it closed around the pedicle and severed it. The tumor was seized with a volsella forceps and delivered. The index-finger could now be passed into the cavity of the uterus. The pedicle was situated on the posterior wall, near the fundus. The tissues at that point were soft and friable, but the remainder of the surface of the uterine cavity appeared to be free from disease. The stump was cauterized with nitric acid and a two-grain opium suppository placed in the rectum. Convalescence was rapid and satisfactory.

On section and close examination the specimen very much resembles placental tissue, and the microscope shows typical placental villi in its structure. It is the *placental polypus* described by C. Braun in 1851, and somewhat resembles the *fibrinous polypus* of Kiwisch, who thought that these polypi might arise from long-persistent hemorrhage, a kind of apoplexy of the womb, a large coagulum forming, the upper part consisting mostly of fibrin and adhering by a stalk to the uterine wall, whilst the lower consists of red, soft coagulum having a coat of firm fibrin. Scanzoni does not admit this view. He contends that these are cases of abortion, and would therefore fall under the class of placental polypi (Barnes). My own experience agrees with that of Scanzoni. These polypi cause profuse metrorrhagia, and sometimes, as in this case, blood-poisoning.

This case furnishes another strong argument in favor of the entire removal of the decidua or placenta after abortion. Who can tell how many lives are lost, or in how many cases the health is undermined, by a neglect of this procedure? Death would inevitably

have occurred in this case if the uterus had not been emptied. The patient may suffer for months or years as a result of neglect. In this instance the fault was in the patient, for she had been properly advised by her physician. It is true that many cases escape without serious injury; but that does not prove that the principle and practice of immediate removal is not always the safe one, for here is a case where a neglected abortion had apparently passed off safely, but it almost destroyed the patient's life a long time afterwards.

Malignant disease was properly suspected from the rapid development of such grave symptoms, from the general cachectic appearance of the patient, and from the sensation conveyed to the finger when touching the growth *in situ*. But when it was found that it had a limited point of attachment and that the uterine cavity was healthy at all other points, this hypothesis was weakened, and when more careful examination of the specimen and investigation with the microscope showed it to contain placental villi, its benign character was assured.

Dr. MONTGOMERY remarked that in cases in which partial dilatation of the uterine canal had been accomplished before the patient presented, the best instrument to continue the dilatation is the mechanical urethral dilator of Dr. A. H. Smith.

HAIR-PIN IN THE UTERUS.

Dr. B. F. BAER exhibited a hair-pin removed from the uterine cavity of a patient sent to him by Dr. Pancoast, of Camden, New Jersey. The woman, believing herself to be pregnant, had tried to produce an abortion by inserting the pin by grasping the points and inserting the blunt end. The patient had obtained a view of the parts in a mirror placed upon the floor. The presence of the pin was readily detected by the uterine sound. He at first thought of dilating with tents, but, the patient being greatly alarmed and very importunate, he used the steel dilator. One point of the pin became embedded in its descent in the tissues of the cervix, and required dissection to release it.

Dr. WHARTON SINKLER exhibited a hair-pin removed from the vagina of a patient who had tried to introduce it into the uterus to produce abortion. She had failed in her purpose, and had also failed to remove it from the vagina. The doctor found the points of the pin widely separated, presenting downward, and hooked into the walls of the vagina. By bringing the points close together, the pin was removed without difficulty. It had been in the vagina for some time.

Dr. MONTGOMERY stated that, while a student, he had seen a hair-pin removed from a vagina. It was thickly incrusted with a calcareous deposit.

PHILADELPHIA CLINICAL SOCIETY.

MEETING OF OCTOBER 24, 1884.

DR. BEATES in the chair.

DR. E. E. MONTGOMERY reported a

CASE OF EXTRA-UTERINE PREGNANCY—RUPTURE, PERITONITIS, RECOVERY.

March 19, 1884.—Mrs. M., has had four children and two miscarriages, the last miscarriage occurring some four months since. She has for several years suffered from chronic phthisis. Menstruation was absent for two periods, but two weeks ago she had a bloody discharge for several days. Although she had been suffering from the phenomena usual to her in early pregnancy, she then concluded that she was not pregnant.

On the 18th, after a fright, she was taken with severe pain in the right side, which, continuing to grow worse, was attended by frequent micturition, a sensation in the pelvis of weight or bearing down, intermittent vomiting, and a serous vaginal discharge. Her husband called at 3 A.M. to-day (March 19), informed me she had cramps, and asked for a prescription for her relief. I gave a prescription containing morph. sulph., gr. $\frac{1}{8}$ to each dose, to be given every two hours until relief.

I saw her at 8 A.M., when she was quite pale, complaining still of pain in the right inguinal region. As I had a clinic at 9 A.M., I made a hurried visit, injected morph., gr. $\frac{1}{4}$, hypodermically, and ordered ℞ Quin. sulph., gr. ij, ext. opii, gr. ss, in pill, every three hours.

5 P.M.—Pain somewhat relieved, stomach very irritable, would retain nothing, pain greatly increased by vomiting, face pinched, pale, and anxious-looking, lips bloodless, pulse 90. Bimanual examination disclosed the uterus slightly enlarged and retroverted. Douglas's cul-de-sac presented a mushy or doughy sensation; on the right side could be felt a small, irregular-sized mass, which was diagnosticated to be an escaped fœtus from a tubal pregnancy. The pills were discontinued, and ext. opii, gr. j, in suppository, substituted, to be given every six hours, and an alkaline mixture and f℥ss each of milk and lime-water were given every three hours by the stomach.

20th.—She slept poorly, but does not suffer so much from pain. There is marked tenderness over the lower part of the abdomen, more marked upon the left side. Examination per vaginam; the mass is felt posterior to the uterus, and is quite hard and tender upon pressure. The uterus is fixed; pulse, 90; vomited once. She has been kept perfectly quiet; the bladder relieved by the catheter. ℞ Quin. sulph., gr. v, ext. opii, gr. iss, in suppository, every six hours.

21st.—General condition better, though she slept but little. The introduction of the suppositories was attended with so much pain that they were discontinued, and morph. sulph., gr. $\frac{1}{6}$, with quin. sulph., gr. ij, given every three hours, by the mouth.

22d.—Some sickness of the stomach; pulse 88, temperature normal; very nervous, easily disturbed. Abdomen still tender to pressure. Returned to the use of the suppositories. Slept well last night after tr. op. deod., gtt. xxv, were given.

24th.—Temperature normal. Pulse 80. Abdomen still tender, especially over the lower portion and left side; movement attended with pain. The suppositories induced so much pain that they were discontinued, and tr. op. deod., gtt. xxx, given by the mouth every three hours.

Subsequent to this date the convalescence was gradual. She regained her strength very slowly. She left the city the latter part of July, returning about the middle of September again pregnant.

Upon examination a few days ago the uterus was found enlarged to the usual size at two months, and posterior to it could be felt a smaller mass, in which the remains of the former gestation were evidently encapsulated.

In such cases, it becomes an important question to decide when we should proceed to surgical measures.

Notwithstanding the successful termination of this case, I would not uphold the treatment as the one most likely to yield a favorable result.

Had the symptoms of shock and internal hemorrhage persisted during the third day, as upon the second, it was intended to make an abdominal incision, remove the fœtus and effused blood, and ligate the bleeding vessels. Such a course, pursued with the advent of the characteristic symptoms, would, without doubt, decrease the mortality of the accident.

Dr. MONTGOMERY also reported, for Dr. JAMES SIBBALD,

A CASE OF EXTRA-UTERINE PREGNANCY TREATED SUCCESSFULLY BY ELECTRICITY.

Mrs. R., æt. 34 years; a woman weighing one hundred and seven pounds, of spare build and exceedingly nervo-bilious temperament. Was married when twenty-one years of age, and had a miscarriage about five months subsequently, since which time (for thirteen years) she was never pregnant, although very desirous of becoming so.

Her menstrual periods were always regular and natural up to June 16, 1884, at which time there was no sign of menstruation. One week later she commenced feeling sick in the morning, and also complained of soreness, with decided tenderness, on pressure over the right inguinal region, which gradually increased in severity. At the same time bloody discharges would appear, with no regularity, every week or two, lasting from a few hours to several days.

On July 3, while standing in the street dealing with her butcher, she was suddenly seized with a violent pain in the abdomen, which caused her to fall in the street. She was picked up and carried to her bed. Morphia was administered hypodermically and poultices applied for six days before the tenderness subsided. For the next three weeks there was more or less tenderness over the right inguinal region.

On August 4 (just one month after the first attack) she had a second attack of local peritonitis, which lasted five days. At this time she was sweeping the floor, when she suddenly fell, overcome by the severe abdominal pain.

After the acute symptoms of the first attack had subsided, a vaginal examination revealed a soft mass on the right side of the uterus, very sensitive to pressure, and displacing that organ to the left. The sound was passed cautiously into the uterus a distance of over four inches, without obstruction. These facts, in connection with the cessation of menses, morning sickness, some enlargement and soreness of breasts, with occasional bloody discharges from the uterus, warranted a diagnosis of extra-uterine pregnancy.

On August 18 Dr. Montgomery saw the case in consultation, and coincided in the diagnosis. He advised the destruction of the fœtus, which was now in about the eleventh week of gestation, by means of electricity. Eight applications of the battery were made, which had the desired result. The mass is slightly perceptible on examination at the present time, the womb being still displaced to the left side. Menstruation has returned twice since, being perfectly normal, and no inconvenience is now experienced.

DISCUSSION.

Dr. JOHN B. ROBERTS coincided with Dr. Montgomery as to the advisability of performing laparotomy where the symptoms of rupture continued urgent.

Dr. G. BETTON MASSEY, replying to a question put by Dr. Barton, said that the form of electricity depended on the work to be done in a given case. Electricity is called upon for two separate and distinct functions in extra-uterine pregnancy,—to kill the fœtus and to produce its absorption. In the former case a somatic death of the germ contained in the tumor is desired; in the latter merely a molecular death or change. In this latter instance, where the death of the fœtus has occurred, and we merely wish to promote its absorption, together with any effused blood or other material, the indications are almost exactly similar to those of any other intra-abdominal tumor: the current with greatest electrolytic

power—the galvanic—is to be preferred. On the other hand, if we wish to arrest the onward progress of life in the fœtal mass in the interest of the unfortunate mother, that current which will accomplish this object with least danger to the mother is to be preferred. This is undoubtedly the faradic current. Shock must be the quality of value here. It is simply a question of transmitting a sufficiency of shock through the abdominal walls of the mother to the more vital parts of the fœtus. If the ordinary faradic battery were not strong enough, the gravity of these sad cases would even warrant the building of a weak dynamo for the special purpose. As to the method of application: the external percutaneous passage of the current by moistened electrodes would seem to be the best; a vaginal electrode might be used, however, the principal endeavor being to send the current directly through the tumor. Drs. Thomas and Mundé have recently reported a number of cases to the American Gynæcological Society, where successful results had followed the use of electricity. To his mind, however, their remarks, as reported, lacked definiteness in this matter of the choice of current and the exact object desired in the individual case. Dr. Thomas does not advise the use of electricity after the fifth month, but an operation instead. Possibly he anticipates difficulty in then producing death, but this could be overcome by increasing the strength of current in the manner above indicated; even if an operation were afterwards performed, the previous arrest of the placental circulation might be of value.

In response to inquiries from Drs. Hall and Roberts, Dr. Massey said that an insulated sound with free extremity would form an excellent vaginal electrode, but that the use of acupuncture needles is totally unnecessary.

Dr. Montgomery, in closing the discussion, said that he had applied one electrode in the vagina in contact with the uterus, and the other over the hypogastrium. He thought acupuncture unnecessary, though it was formerly the practice to use this procedure, as it was liable to cause peritonitis from the liquor amnii escaping into the peritoneal cavity. There is but little difference in the use of either current. There were two reasons why electricity was unavailable after four and a half or five months. The liability to rupture was greatest in the early months,—before the third month. After that we may as well allow the case to go on to a later month, as an operation will be necessary anyway. A large fœtus is more dangerous to the mother after loss of vitality, and cannot be allowed to remain. Although the woman had fallen in the case related, he thought the fœtus was still living, and therefore advised the electricity with the direct purpose to kill. Subsequently the tumor became smaller. The fœtus and appendages become encapsulated in the abdominal cavities of the mothers in these cases. There is no advantage in destroying the fœtus prior to operation.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held November 6, 1884, Fordyce Barker, M.D., LL.D., President, in the chair.

The first scientific paper of the evening was read by Dr. R. W. Amidon, entitled

THE PATHOLOGY OF SENSORY APHASIA, WITH A SPECIMEN.

The history of the case which had come under Dr. Amidon's observation was, in brief, as follows: The patient was a female, aged 60 years, who had been well up to the time of the menopause, nine years before. Since then she had suffered from flatulent dyspepsia, headache, and other evidences of a neurasthenic condition. Six weeks before Dr. Amidon saw her (which was in June, 1883), she had had a severe headache on the left side, which continued for three days, when she became excitable and flighty in mind, and vomiting occurred. When Dr. Amidon made an examination of the patient he found the right pupil larger than the left, the tongue deviated slightly to the right; the right hand was tremulous and had lost strength, but there was no marked disturbance of motility; the fundus oculi appeared healthy, and acuity of vision was normal. The patient gave inappropriate answers to questions, was unable to count or say letters, could not be induced to write, but she could speak intelligibly of her own accord. She recognized all her friends except her husband, and she called her son "father." Hearing was apparently normal. She could sing correctly. After this she was subject to periodical attacks about once a month, when she would utter a cry, throw up the right hand, then the mouth would be drawn to the right, and a general convulsion would follow, sometimes with involuntary evacuations. February 15, 1884, she had one of these attacks. The next day she was comatose, and died in that condition.

At the autopsy the kidneys were found to be the seat of advanced interstitial changes. The right cerebral hemisphere was normal; on the surface of the left there was an irregular depression caused by destruction of cerebral tissue, involving the inferior parietal lobule, the angular gyrus, and the second occipital and first temporal convolutions. The arteries in this region were atheromatous, and one was entirely occluded.

Dr. Amidon then quoted cases, illustrated by diagrams, which had been reported by Balzer, d'Heilly and Chautemesse, A. B. Ball, Chauffard, Giraudeau, Seppilli, and about fourteen others. Of the twenty-four

cases reported, in eight the lesion affected both the visual and auditory cortical regions of the left hemisphere, and there was both word blindness and word deafness. In two cases the area of vision alone was involved, and there was word blindness. In fourteen there was lesion of the auditory region, with word deafness.

Dr. Amidon gave the following conclusions: That *word blindness* is an incapacity to understand speech, printed or written, vision and intelligence being preserved. It is generally dependent upon destructive lesion of parts of the inferior parietal lobule, angular gyrus, and second occipital convolution of the left side. Its mechanism consisted in an abolition of the transformation of written words into verbal images.

Seppilli's conclusions with regard to *word deafness* were that this condition represented a lesion of speech clinically and anatomically distinct from aphasia. It was often associated with amnesic aphasia, motor aphasia, or word blindness. The lesion consisted in a destruction of the first and second left temporal convolutions. The mechanism of word deafness is due to complete abolition of the power of transformation of spoken words into verbal images. Word deafness he considered an indication of great value in locating a lesion of the left temporal lobe.

The second scientific paper of the evening was by Dr. FRANK H. HAMILTON, on

ASIATIC CHOLERA AT SUSPENSION BRIDGE IN 1854, AND ITS LESSONS—WHAT WE KNOW OF CHOLERA.

The author said the present paper was the fulfilment of a promise to the editor of the *Buffalo Medical Journal*, in 1854, sometime to write a paper on the Asiatic cholera as it had prevailed at Suspension Bridge that year. After directing attention to the extreme fatality of the epidemic and its rapid spread among the workmen at Suspension Bridge, the author ascribed the great mortality to the combined effect of elevated temperature, moisture, and recently-upturned alluvial soil. It was at the request of Dr. Rogers that Dr. Hamilton and two other physicians had visited the patients during this epidemic. The following lessons which he had drawn from it were not presented as new, but as being entitled to special notice, in view of the fact that we were liable to have cholera imported into this city at any time. His opinions would be expressed chiefly upon the question of what is the present state of knowledge of the nature, the etiology, the mode of propagation, and the treatment of Asiatic cholera.

First, Dr. Hamilton claimed that we have no positive knowledge of the existence of a specific cholera germ. In 1854, Pacini, an Italian physician, described a germ to the presence of which he ascribed the development of cholera, and recently Koch had discovered the "comma bacillus," which he regarded as the true cholera germ; but after marshalling the facts for and against Koch's hypothesis, and the conflicting observations of others who had investigated the subject, the author stated that, with regard to the theory of Koch, that the comma bacillus was the cause of cholera, he felt justified in the assertion that the claim had not been established.

Even if it were determined that the comma bacillus were always present in cholera, but never in other disease or in health, that of itself would not decide that the bacillus and cholera stood in the relation of cause and effect. Again, the theory was also defective in that it had not been shown that the introduction of this germ into the animal system would produce cholera. The inoculations by Koch himself, practised upon the lower animals, had been barren of results. Again, if it were established that a microbe was the cause of cholera, the question would remain to be answered, Which of the microbes hitherto described, or yet to be discovered, would prove the efficient agent? But it might still remain to be proven, should the experimentalists succeed in producing cholera by the introduction of a fluid containing a germ or germs into the system, whether the efficient agent were the fluid or the germ. It might be the fluid containing the microbe which was the cause of cholera, this fluid having taken on properties which no microscope could detect. The author did not wish to be understood as underestimating the importance of microscopical studies; much useful information had been derived from the microscope in the study of disease, but, so far as the cholera or other epidemic infectious diseases were concerned, microscopists had not taught us any important lessons, either with regard to their cause or their prevention. Germicides kill the microbes when attacked outside of the body, outside of their native soil, but within the body these remedies had no effect upon them. Consequently, patients continued to die of cholera after the discovery of microbes. Moreover, it had not been positively proven that the active agent in the production of the disease resided in the intestines; the symptoms would indicate that it might also exist in the blood.

The cholera germ (using this term in its general signification) might be conveyed from place to place by the clothing or any other textile fabric, by articles of food, or water, or animate or inanimate substance. It might be conveyed a considerable distance by the air, —how far it would be difficult to say; probably much would depend upon the force of the wind and other atmospheric conditions. He had reason to think it could not be thus conveyed farther than a mile or two. The theory of Koch, that the germ only found its way into the system through the mouth and

stomach, was corollary to his theory of causation by the comma bacillus, and that introduction of the virus through the mouth and into the stomach might be one of the means of propagation could be admitted, but that it was the only means the history of epidemics showed not to be true. It was not necessary to assume that because the intestinal secretions were changed, or the mucous membrane congested, the virus was originally implanted in the intestinal canal. The blood and the renal secretion also underwent changes quite as marked as those which took place in the intestinal secretions.

Although the cholera virus were received into the human system, it need not necessarily give rise to cholera. It seemed probable that every person living in a cholera atmosphere received more or less of the virus into the system, but only a small proportion of these persons took sick and died. It was true of all the infectious diseases, that the reception of the virus into the system did not necessarily produce that specific disease. It was also true, however, that a large proportion of those exposed to infectious diseases became infected, whereas only a small proportion of those exposed to cholera took the disease. A suitable soil was necessary. Cholera also differed from other infectious maladies in that one attack did not insure protection against another.

The conditions which protected against cholera were all those which went to prevent disturbance of the alimentary canal; also the avoidance of impure air, overcrowding, bad ventilation, decaying vegetable or animal matter, stagnant water, a warm and moist condition of the atmosphere. The most efficient agent for the propagation of the disease seemed to be the vapors rising from freshly-exposed soil and decaying animal and vegetable matter, together with a warm and moist atmosphere. That filth was not the only efficient cause of the spread of the disease was shown by the fact that during the epidemic at Buffalo those persons living in dirty shanties on a sandy soil by the lake escaped. But there were instances on record which went to show that a favorable condition of the soil and atmosphere alone would not check the spread of the disease if other local conditions sufficiently favored its spread.

The profession had long sought for a specific against Asiatic cholera, but there were really but very few specifics against any diseases, and none had yet been found for infectious diseases. But in the case of scarlet fever, etc., the disease would run a certain course, and we could only seek to conduct the case to a favorable issue; whereas in cholera, if we took it in time, we could often abort it. It was seldom, however, that a patient was saved to whom remedies were not administered until after the period of collapse had arrived. The remedies which had proven most successful were those which had long been known to be most successful in the treatment of diarrhœa, cholera morbus, and analogous affections. The most efficient means prior to the stage of collapse were opium and rest. Dr. Hamilton preferred opium in the solid form to morphine. The patient would be more likely to recover were he removed to a region not favoring the propagation of cholera, and usually it would be found that the disease would not be spread in his new domicile.

It was believed that the cholera was brought to Suspension Bridge by some immigrants, but these people did not, so far as was known, suffer markedly from the disease, either before their arrival at Suspension Bridge or after their departure, which went to prove that the rapid spread and fatality of the affection among the laborers there was due to the condition of the soil and atmosphere. Again, in only a few instances, and in which the topographical conditions were favorable, was the cholera virus carried to and spread in neighboring localities.

Should cholera appear in this city, would it prove as fatal as it had done in Naples and the south of France? Dr. Hamilton answered in the negative, and for the reason that our climate is more favorable, our system of sewerage better, and we had efficient sanitary measures for the prevention of the spread of the disease. He referred to the success attending the efforts of the sanitary commission in stamping out cholera from Blackwell's Island in 1866, and spoke of the efficient work done by Dr. Yale, then one of the house staff.

Dr. L. M. Yale gave some of the circumstances attending the outbreak of cholera on Blackwell's Island in 1866–67, at which time he was interne in one of the institutions. The epidemic was preceded by great heat, by a tendency to diarrhœal affections in the inmates, and it had been the custom to allow the dejections to remain in a tub in the room over night. Removing the unfavorable conditions, the epidemic, which had carried off many of the inmates in the workhouse, was almost immediately and completely checked.

Dr. Francis Delafield thought it would be conceded that cholera was due to some specific virus, and that without that virus cholera would not develop, no matter how favorable the other conditions might be for an outbreak of that disease. As to what was the nature of the specific poison of cholera, after the fashion of the present time to ascribe disease to the presence and development of a germ, cholera had been ascribed by Koch to the comma bacillus. It took time to decide whether a fashion were a good or a bad one. He spoke of the difficulties attending investigations into the bacterial cause of disease, and said that reliance could not be placed on all pretended experiments alike. He should

consider the conditions favoring the development of cholera to be those which also favored diarrhœal affections. He was of opinion that quarantine would not prove an effectual barrier to the spread of cholera.

Dr. A. L. Loomis was of the impression that the specific poison of cholera, like that of typhoid fever, must undergo changes after leaving the human system before it would become able to impart cholera to the healthy person. He did not believe that cholera could be developed spontaneously, but that its native place was Bengal, from where all epidemics in different parts of the world could trace their origin. The poison could find admission to the human system by the mucous membrane of either the upper or lower portion of the alimentary tract. It had not been shown that the active specific poison existed only in the secretions from the intestines.

Dr. John C. Peters showed maps illustrating the spread of cholera from India, and also stated that the efficacy of quarantine had been shown in Denmark, where, so long as quarantine was enforced, cholera had never entered. Greece had also found quarantine effectual against the importation of the poison.

REVIEWS AND BOOK NOTICES.

The Brain and the Nerves: their Ailments and their Exhaustion. By Thomas Stretch Dowse, M.D. New York, G. P. Putnam's Sons, 1884.

Under this title Dr. Dowse has given to the world one hundred and fifty printed pages, constituting a very readable book, as also one very well worthy of being read; one from which the medical practitioner can gather grain of value, provided said medical practitioner has wit enough to know good grain from bad. The title of the book is misleading, as it is not upon nervous ailments in general, but simply upon nervous exhaustion, a condition again in most cases misnamed, since exhaustion and debility are two different things, and usually it is nervous debility rather than exhaustion which the practitioner is called to meet.

Of all specialties, that of the nerve-exhaustionist seems to lead to the most reckless and dogmatic statement of untruths or disputed truths; probably because there has been so much fog about the subject that those who study it see things distorted and do not recognize that they are enshrouded by it. In the lack of light, they have cultivated most highly their imaginative faculty, accustomed by habit to the mist. Our writer is no exception to this habitual enfogment.

Thus, he bases his work upon the following with other propositions (the italics are his own): "*That man is the highest type of the combination and correlation of all known and unknown forces.*" (If a force is unknown, how can it be known that it enters into a combination which is unknown?) "*That we call this force nervous or vital force,*"—which is simple nonsense; for how can man, to whom "*this force*" evidently refers, be vital force, or how can a combination and a correlation be force?

Again, "That nervous exhaustion is the forerunner and prime agent in the production of all diseases, functional and organic,"—a proposition which we think most of our readers will consider well adapted to excite laughter.

On page 15 we are told "positively that it is *proved* that chloral excites a toning influence upon the arterial web." On page 121, that "it (chloral) has the effect of lowering the tonus of the body and of breaking up the red blood-corpuscles;" that it is also "prejudicial to blood-oxidation and lymph corpuscular assimilation,"—dogmatic assertions, partly true but largely false, worthy to be enframed and set as up frightful examples to young medical writers in the same way as the drunkard adorns the labor of the temperance orator. If our author in his next edition would control this his almost hysterical tendency to literary positivism, and not say "nervous exhaustion is *invariably* associated with rapid breathing," when he means or ought to mean is frequently associated, and would avoid all exaggeration, he would make his book more trustworthy, although perhaps less amusing.

Transactions of the American Gynæcological Society. Vol. VIII., for the Year 1883. New York, D. Appleton & Co., 1884. 8vo, pp. 276.

Owing to an oversight, we neglected to notice the appearance of this handsome volume of Transactions at the time it was published. The report of the meeting held at Philadelphia, which appeared in our columns at the time, will serve as an index to the present issue, which contains thirteen essays upon practical topics connected with gynæcic surgery, and two biographical memoirs, besides the usual lists of officers and members, minutes of meeting, and index. The Society is to be congratulated upon the handsome form in which the proceedings are issued, and the editor, Dr. Foster, deserves especial credit for the more prompt appearance of this than had heretofore been the practice with former volumes.

Post-Nasal Catarrh and Diseases of the Nose causing Deafness. By Edward Woakes, M.D. Illustrated. Philadelphia, P. Blakiston & Co., 1884. 8vo, pp. 224.

This is the third edition of Woakes's unpretentious little work, which was received with such favor by the profession. Although lim-

ited in its topics selected for discussion to a department of disease which is considered subsidiary to the special domain of the aural surgeon, its subjects are by no means unimportant; and we may be pardoned the statement that it has been principally through the activity of American writers and workers that their proper relations and significance have become recognized. The present work is especially concerned with the author's methods of treatment, which in some instances differ from our own, whether for the better or worse experience will rapidly determine. The chapters devoted to the Pre-Catarrhal State and Taking Cold are of special interest as an indication of the tendency which now exists towards preventive medicine. Whether the treatment be followed or not, no one can read the work without being interested and benefited by it.

GLEANINGS FROM EXCHANGES.

Vogt's Method of Resection of the Astragalus.—An anterior cutaneous incision is made from the tibio-tarsal articular line on the external border of the extensor communis, and directed longitudinally on the tibio-tarsal articulation and dorsum of the foot to Chopart's articulation. The subcutaneous cellular tissue, aponeurosis, and annular ligament are divided, the tendons of the extensor longus digitorum are separated carefully from the subjacent tissues and held firmly to one side, the extensor brevis digitorum is incised and drawn to one side upon the external lip of the wound, the external malleolar artery, and the accompanying veins, are divided between two ligatures.

The articular capsule being incised longitudinally as far as possible, the insertions of the capsule and its ligaments are detached on each side by the raspatorium, the head and neck of the astragalus are denuded, the astragalo-scaphoidean ligaments are divided transversely, so as to disengage the anterior part of the astragalus. Now an incision is made from the middle of the anterior longitudinal incision, which is laterally transverse, and in the adult about ten centimetres long, terminating under the point of the external malleolus, and the soft parts are gradually divided down to the astragalus without interfering with the peroneal tendons.

The foot being forcibly supinated, the peroneo-calcanean ligaments are divided close to the malleolus, and a sharp-pointed bistoury cuts the ligamentous attachment of the sinus of the tarsus, using also, if necessary, a delicate pair of scissors.

The astragalus is brought forward in rotating outward the supinated foot, by seizing the neck of the astragalus with a davier, or by the aid of an elevator placed beneath the bone. A fine pair of scissors introduced between the internal malleolus and the astragalus cuts the large insertion of the internal lateral ligament to the astragalus; a new traction, effected by pressure, carries the astragalus so forcibly outward that its last attachments to the calcaneum at the posterior astragalo-calcanean articulation can be easily divided.

After the ablation of the astragalus, the whole of the articular cavity is exposed, the synovial membranes can be extirpated, and it is easy to remove all parts of the tibia and calcaneum that may be suspicious. After drainage and suture, the superior surface of the calcaneum adapts itself so exactly to the malleolar surfaces as to leave no cavity.—*Journal of the American Medical Association.*

Oil of Gaultheria in Rheumatism.—In the *New York Medical Journal* for November 8 appears an article entitled a New Specific for Rheumatism, in which Dr. H. H. Seelye reports the results obtained from oil of gaultheria given in one hundred and eighteen cases of acute articular rheumatism. It can be administered in capsules, alone or with salicylate of sodium, or in soda-water, but the preferred method was in an emulsion in glycerin and water. From ten to twenty minims were given every two hours during the day, and at intervals of three hours during the night. All forms of rheumatic pain seemed remarkably influenced, but its effect was most marked in acute inflammatory cases. The tendency to cardiac complications seemed not to be increased. The success was so gratifying that further trial of the remedy was strongly urged.

MISCELLANY.

Munificent Gift to the German Hospital.—On the 16th instant the new wing of the German Hospital of this city was opened with appropriate ceremonies, in the presence of a large number of distinguished visitors, in the chapel of the new three-story building, which adjoins the old, extending to the south.

Addresses were made by Mr. Lankenau, President of the Board, who formally turned over the building to the Trustees, the donation being acknowledged by Col. M. Richards Muckle, after which other addresses were made, and the company proceeded to inspect the improvements.

Over the entire old portions of the main building a mansard story had also been erected, and above the extreme western part an entresol has been constructed for storage purposes. Over this is a story fourteen feet high in the clear, containing seven rooms. The old, dark staircase has been opened up to the roof, where a ventilating skylight has been placed, giving a cheerful aspect to the stairs and corridors. The new mansard story

over the eastern portion of the building is seventeen feet high, divided into thirteen apartments. One of these, facing the south, is the Convalescent Ward, twenty by forty feet, opening into a sunny veranda forming a solarium in winter. From this room a fine south view of the city is afforded. The eastern staircase in this portion of the building was also carried up with roof skylight.

Set in the roof or loft are three iron tanks, each sixteen feet long, eight feet wide, and four feet deep, holding in the aggregate nine thousand gallons of water. Besides abundant fire-connections, the hospital is supplied with seventy-two fire-buckets and three Climax chemical fire-extinguishers.

The basement story of the main building has also been materially improved, the kitchen having been enlarged and a new cooking-range, fourteen feet long, placed in it, together with a number of steam-tables.

Running south, at right angles with the old portion, situated at the southwestern corner of the main building, is the new wing, one hundred and twelve feet long and thirty-three feet wide. This extension is surrounded by an area twelve feet in width, giving light and air to the basement, which is five feet below the surface and five feet above it. The walls of the area are built with massive mason-work of Stockton stone, laid in regular range-work, coped with dressed granite, and surmounted by a neat, open wrought-iron railing, the pavement being laid with North River flagstone. The basement is ten feet in the clear, with central corridor, having rubbed flagstone floor, with pipe ducts in the centre. Upon each side of this passage are located apartments for the domestics, some twelve rooms in all.

Above the basement are the three upper stories, each fourteen feet ten inches high, and the mansard story, thirteen feet six inches in height.

At the intersection of the corridors of the several stories of the old and new buildings are the baths and water-closets, all arranged in the most convenient and complete manner. The floors are laid with slate upon brick arches, the plumbing-work being executed with the best materials in a substantial manner, the pipe being exposed in most cases.

The main grand staircase, sixteen by thirty-six feet in size upon the plan, divides the old and new buildings. This portion of the structure it was thought advisable to construct fireproof. The materials employed therein are therefore iron beams with brick arches. The "horses" and framings of the stairs and platforms were built with iron beams, slate risers, steps, platforms, and flooring, and the soffits and ceilings are plastered upon wire mesherwork. All the balusters, hand-railing, newel-posts, and wainscoting are finished in white oak with ash burl panels.

This portion of the building is surmounted by the cupola, having a square base at the roof of twenty-six feet, with hold balustrading and pedestals and arms at the four corners. From this base the cupola proper starts. It is octagonal in form, and finished in the full order of the Ionic style of architecture, having on each of the eight corners a column, with its entablature and blocking courses, terminating with a domed roof and finial, with golden vane and the cardinal points, the top of which stands two hundred and fifty feet above tide-water level. From this balustrade floor is afforded a magnificent view of the entire city.

On the first, second, and third floors of this new wing are wards thirty by eighty-six feet, each having accommodations for sixteen beds. On each of these floors are two anterooms for nurses, kitchens or sewing-rooms, and entrances to the passenger elevator. The first and second floors have bay-windows on the southeast, with seats as rests for the sick. There are large ventilating-rooms at each corner of the wards, those on the north side having steam jets in them. Open grates are set in the south corners. Each ward has ventilating registers, each fourteen by eighteen inches, arranged for top and bottom draughts. For summer use, gas-folding brackets swing into flues in the walls, and are encased in projecting bent-glass screens to keep the heat from the room, while the lower portion is open to draw off the impure air into the flue. This arrangement not only frees the room from the heat of the jets, but the flame acts as a ventilating agent, the heat creating the current of the draught.

There are seven large windows in each of the east and west walls, having double sashes to equalize the external temperature. The transom sashes of these windows are filled with stained glass, with figures of water-plants and other objects neatly designed.

All the steam radiators in the wards are supplied with fresh air from the external atmosphere by open cast-iron flues, walled in, having open gratings in the external walls, and cast-iron pivot doors to close off the draught at pleasure inside. These flues supply the lower portion of the radiator, in place of being set at the top.

The wood-work is of ash, with hard shellac finish, and the washboarding was done with cement.

The operating-room and clinical amphitheatre is situated upon the west of the new south wing, and is entered internally from the main staircase, and externally upon a neat iron stairway. This room is a full circle, the floor being twenty-six feet in diameter. The centre and eastern half is occupied by the operating-space proper. Ample light is afforded by the skylight in the dome or ceiling and one of the Siemens regenerative gas-burners, which consumes fifty cubic feet of gas per hour and gives a light of five hundred

candle-power, and is useful in improving the ventilation. There are also ample side-lights. The floor is laid with encaustic tile, and the walls up to the spring of the cornice are lined with light glazed tiles having an ornamental border. The seating is in ash, with capacity for sixty persons. Attached to this room on the east is a private apartment for the use of the medical staff.

All the buildings are constructed of strong, durable Yardleyville sandstone, laid in range-work, drafted and tool-pointed with cement. It has a warm tone of color, pleasing to the eye. The interior of the walls is faced with hard brick, allowing an open space of two inches to keep the inside dry and to break the external heat, while the roof is triple-pitched and covered with Peach Bottom slate; the top or upper deck has a line of ventilating openings in the cornice-mouldings for drawing off the heat of the lofts. This arrangement has been employed in all of the roofing of the old and new buildings. The dome of the operating theatre is covered with a galvanized iron-pointed pattern of shingling. With the exception of the main wing building, where most of the cornice-work is executed in stone, the cornices of the entire buildings are of galvanized iron.

The fire-escape is on the southwest corner of the new wing building, easy of access. It extends through the several floors, and is constructed of cast and galvanized iron.

The improvements, including the new buildings for the hospital proper, the boiler-house, laundry, etc., and for the Mary J. Drexel home and the grounds, represent a total valuation of more than six hundred thousand dollars, the free gift of Mr. John D. Lankenau, the President of the Board of Trustees.

THE HYDROCHLORATE OF COCAINE has raised quite a furore. Abundant experience has already demonstrated its value as a local anæsthetic in eye-surgery, and it has also been used successfully injected into the skin to facilitate removal of small tumors.

THE first volume of the "American System of Practical Medicine," edited by Prof. Wm. Pepper, it is announced, will be ready for subscribers February 1, 1885.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM NOVEMBER 9, 1884, *TO NOVEMBER* 22, 1884.

MCKEE, JAMES C., MAJOR AND SURGEON.—Leave of absence extended one month. S. O. 273, A. G. O., November 20, 1884.

BYRNE, C. C., MAJOR AND SURGEON.—Granted four months' leave of absence from November 16, 1884. S. O. 265, A. G. O., November 11, 1884.

GODDARD, C. E., MAJOR AND SURGEON.—Assigned to duty at Fort Yates, Dakota Territory. S. O. 138, Department of Dakota, November 15, 1884.

TREMAINE, W. S., MAJOR AND SURGEON.—Granted leave of absence for one month, on surgeon's certificate of disability. S. O. 233, Department of the East, November 12, 1884.

WILSON, WILLIAM J., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for four months, with permission to go beyond sea, to take effect when his services can be spared by his department commander. S. O. 262, A. G. O., November 7, 1884.

COWDREY, S. G., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 237, Department of the East, November 17, 1884.

HAVARD, VALERY, CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for four months, permission to go beyond sea, to take effect when his services can be dispensed with at his present station. S. O. 268, A. G. O., November 14, 1884.

SHUFELDT, R. W., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty as post surgeon, Fort Wingate, New Mexico. S. O. 217, Department of Missouri, November 4, 1884.

TAYLOR, A. W., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Fort Omaha, Nebraska, and ordered for duty at Fort D. A. Russell, Wyoming Territory. S. O. 101, Department of the Platte, November 19, 1884.

OWEN, WILLIAM O., JR., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Fort Canby, Washington Territory, and ordered to Fort Spokane, Washington Territory, for duty. S. O. 169, Department of the Columbia, November 4, 1884.

PHILLIPS, JOHN L., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Assigned to duty at Fort Keogh, Montana Territory. S. O. 134, Department of Dakota, November 5, 1884.

LIST OF CHANGES OF STATIONS OF NAVAL MEDICAL OFFICERS FROM NOVEMBER 9, 1884, *TO NOVEMBER* 22, 1884.

GROVE S. BEARDSLEY, promoted to the grade of medical inspector, April 24, 1884, November 14, 1884.

P. A. Surgeon A. C. HEFFENGER, duty at Portsmouth, New Hampshire, continued till December 12, 1885, November 11, 1884.

Assistant-Surgeon F. W. F. WIEBER, to the Receiving-Ship "Vermont," at New York, November 12, 1884.

P. A. Surgeon HOWARD E. AMES, detached from the Greely Relief Steamer "Bear," and assigned to special duty in New York, November 17, 1884.

Surgeon GEORGE A. BRIGHT, detached from the "Galena," and placed on waiting orders, November 19, 1884.

Medical Inspector C. J. CLEBORNE, to duty at Philadelphia, Pennsylvania, as member of medical examining boards, November 21, 1884.

Surgeon F. L. DU BOIS, when detached from the Naval Examining Board, November 29, is ordered to the "Galena," November 20, 1884.

P. A. Surgeon EDWARD H. GREEN, detached from the Greely-Relief Steamer "Thetis," and assigned to special duty in New York, November 17, 1884.

Surgeon J. H. HALL, detached from Navy-Yard, Mare Island, and assigned to duty at the naval hospital at that yard, November 19, 1884.

Surgeon JOSEPH HUGG, to the "Minnesota," as relief of Surgeon Woolverton, November 15, 1884.

Assistant-Surgeon WILLIAM MARTIN, to special duty in connection with the New Orleans Exposition, November 19, 1884.

P. A. Surgeon F. S. NASH, detached from the Greely-Relief Steamer "Alert," and assigned to special duty in New York, November 17, 1884.

Surgeon W. J. SIMON, to the Philadelphia Hospital for treatment, November 17, 1884.

Surgeon T. WOOLVERTON, detached from the "Galena," and placed on waiting orders for sea-service, November 15, 1884.

PHILADELPHIA MEDICAL TIMES.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON BLEPHARITIS MARGINALIS,—INFLAMMATION OF THE MARGIN OF THE EYELIDS.

Delivered at the New York Eye and Ear Infirmary

BY W. F. MITTENDORF, M.D.

GENTLEMEN,—Among all affections of the eyes, those of the lids, and especially those affecting their free margin, are the ones most frequently met with. This is due, to a great extent, to the exposed position of the lids, and to the large number of glands which are found, especially along their free edge.

Such diseases are not only of frequent occurrence, but will also prove, at times, extremely obstinate to treatment; they are a source of great annoyance to the patient, on account of the unsightly deformity accompanying them. Their treatment will therefore be a matter of great importance not only to the specialist, but also to the general practitioner.

You will remember that, surrounding the eyelashes, the free edge of the lids is studded with small sebaceous glands, the function of which is to keep the margins greased, in order to prevent the tear-fluid from flowing over the cheek. These glands have been named after the celebrated Vienna anatomist, Zeiss, and have been called Zeiss's or tarsal glands. An inflammation of them is called blepharadenitis. After a while the inflammatory process must extend to the connective tissue of the lid, and then we have blepharitis marginalis. Another name of the affection is ophthalmia tarsi. But you will readily understand that by this name is meant an inflammation of the entire lid, whereas blepharadenitis indicates an inflammation of a particular portion of the lid. You will very frequently have patients coming to you who have suffered from diseases of this kind not only for months, but even for years. During that time they had been constantly annoyed by the red appearance of the lids, and by the inconvenience of having the eyelashes always glued together and the tears flowing over the cheeks.

Blepharadenitis is, according to the extent to which the lid participates in the inflammation, to be divided into different classes. The common form is characterized by the appearance of small crusts on the free edge of the lid, surrounding the eyelashes. After removing these crusts, we generally find that the underlying skin is red, looks inflamed. During the night the evaporation of the exudation of these inflamed glands glues the lids together, and the patient is unable to open the eyes in the morning. During the day the eyelashes are matted together, and present an unsightly deformity. This is known as *simple blepharadenitis*.

If the process be allowed to go on, the surrounding tissue is apt to break down, and you have the disease complicated with small ulcerations in different parts of the margin of the lids. Removing the crusts which have formed over the parts, you will find that there is a depressed ulcer underneath, which bleeds easily as soon as the crust is removed. This is the *ulcerative form*.

If this kind of blepharadenitis be not promptly treated, the ulcerative process will extend over the entire free margin of the lid, and as a result we shall have cicatricial changes, which produce great deformity by altering the appearance of the entire free margins. This is known as *lippitudo*, popularly called *blear-eye*.

If the skin do not break down, and the infiltration extend to the deeper parts of the free edge of the lid, it will result in hypertrophy, which in some cases exists to a remarkable degree, there being quite a thick elevation along the entire free margin of the lid. This variety is known as *tylosis*.

There is one other form of blepharadenitis, which is not so marked in its appearances, but which often proves to be extremely obstinate. It is apt to occur in persons with a very delicate skin, especially persons with red hair, because they, as a rule, have a very fine skin, and at the free edge of the lid especially so. The least irritation, sometimes even the atmosphere of the room, or slight straining of the eye from work near by, will in these cases produce fine, little scales on the lids: hence this form of the disease has been given the name *squamous blepharadenitis*. In this form we never have ulcerations of

the lids. The principal features are redness and fine, little, flake-like deposits on the free edge of the lids. This form of blepharadenitis is principally found, too, in eyes which have an error of refraction, especially in hypermetropic eyes, or those that are afflicted with astigmatism. In these cases great accommodative efforts have to be made, which lead to hyperæmia of the free edge of the lids and subsequent irritation of the glands, and, as a result, we get this redness and, as a result of the changed secretion, fine scales.

Blepharadenitis in its simpler form is frequently associated with eczematous conditions, and, if the trouble extend from the edge of the lid to the integument we speak of, eczema of the lid. In these cases you will frequently find eczematous patches behind the ear or on other parts of the body. You cannot expect to cure this form of blepharadenitis by local applications; you will have to resort to internal medication besides. But, as a rule, blepharadenitis is due to local causes. In children the lid-trouble is frequently due to phlyctenular conjunctivitis. In this disease there is, accompanying the inflammatory process, an abundant secretion of sharp, acrid tears, which, as they pass over the free border of the lid, cause an inflammation of the glandular tissue, and sometimes, if they reach the cheek, they cause an excoriation of the integument. This condition is very apt to be found in strumous or scrofulous children.

Another milder form is apt to accompany simple conjunctivitis: it will, as a rule, disappear as soon as the exciting cause is removed.

Treatment.—With regard to the treatment of these affections, it must differ according to the cause and nature of the disease. You will readily understand that the first indication for treatment is the removal of the crusts. If you fail to do this, all your local applications can have little or no effect, because they do not reach the seat of the disease at all. This should be done very carefully, after softening them by the use of warm water or olive oil.

In simple blepharadenitis one of the best remedies at our disposal is liquor plumbi subacetatis, which should be used in the following way:

℞ Liq. plumbi subac., f℥j.

Sig.—Six drops to half a tumbler of water. Use as an eye-lotion five or six times a day for four or five minutes at a time.

If you use the lotion stronger than here indicated, it will produce a peculiar, dry sensation of the free edge of the lid, due to the powerful astringent effect of the sugar of lead. This remedy will in a short time remove the unpleasant redness of the lid entirely.

During the night, in order to prevent the gluing together of the lids, as well as to protect the inflamed parts, a very mild preparation of the red oxide of mercury is indicated. The following prescription, which is known as *Pagenstecher's ointment*, will act very nicely:

℞ Hydrarg. oxid. rubri, gr. j;
Vaseline, ℥j.
Fiat unguent.
Sig.—Apply before retiring.

In order to get the full effect of this medicine, it is necessary that the lid be thoroughly cleaned and dried before it is applied. To effect this object, the eye may be washed with

℞ Sodii bicarbon., ℥j;
Aq. camphoræ, f℥viij. M.
Sig.—Use at night.

Having removed all the crusts and washed the free edge of the lid with this solution, the oxide ointment may be applied. The greatest care should be exercised in preparing the oxide of mercury ointment. The druggist should triturate the red oxide with a few drops of the oil of sweet almonds, so as to reduce it to a very fine powder, and then add the vaseline and mix well together. The difficulty of preparing this ointment properly has led us to substitute for the red oxide the yellow oxide of mercury, which is a very fine powder and can be mixed readily with simple cerate or with vaseline. The proportion may be made a little stronger when the yellow oxide is used, because it is not quite so powerful in its action.

℞ Hydrarg. oxid. flavi, gr. iss;
Ung. simpl., ℥j. M.
Fiat unguent.
Sig.—Apply to the edge of the lid before retiring.

An inflammation of the lids of this kind will frequently extend to the conjunctiva, not only from direct extension of the inflammatory action, but also from the fact that the crusts which form on the free edge of the lid fall into the conjunctival sac and act there as foreign bodies.

In this case it is necessary to use a preparation which can be applied in the conjunctival sac as well, and the following prescription has been of the greatest use to me:

℞ Sodii biborat., gr. xx;
Mucilag. cydon.,
Aq. laurocerasi, āā f℥ss;
Aq. camphoræ, q. s. ad f℥iij. M.

Sig.—Use as an eye-lotion three times a day.

This should not only be applied to the free edge of the lid, but some of it should be allowed to enter the conjunctival sac as well.

The action of the cherry-laurel water is that of a mild anodyne, of the mucilage of quince-seeds soothing, of the camphor-water slightly stimulating, while the biborate of soda is astringent.

If the inflammatory process have extended to the integument of the lid, if we have the condition which may justly be termed eczema of the lid (in children arising from scratching the eyelids constantly), it is well to use a preparation which contains morphine or some anodyne, and in this case we can use a stronger preparation of mercury:

℞ Hydrarg. oxid. rubri, gr. v;
Morph. sulph., gr. iss;
Unguent. simpl., ℥ss. M.

Fiat unguent.

Sig.—Apply, after removing the scab and drying the parts carefully, to the excoriated parts.

In the summer, as a rule, I use simple cerate, because vaseline is too soft and will allow the red oxide to precipitate to the bottom of the jar. During the winter the vaseline may be substituted for the simple cerate, as it is softer and more easily applied, and yet not too soft.

That form of blepharadenitis which is associated with ulcerations of the free edge of the lid should be treated in the same manner, but the ulcerated parts should, in addition, be touched once a day with a solid stick of nitrate of silver. In doing this, much care must be exercised only to touch the ulcerations very gently, for, if the nitrate enters the eye, it will prove extremely painful. Applying this every day will, as a rule, lead to a perfect and rapid cure of this otherwise very tedious and troublesome disease.

There is one form of blepharadenitis which we cannot expect to cure entirely, —namely, that in which the free edge of the lid is completely altered. In these cases you can only expect to relieve the trouble partially, allay active inflammation, without, of course, being able to change the cicatricial conditions, and for this purpose I use a salve which is to be applied at night:

℞ Hydrarg. oxid. rubri, gr. ii;
Liq. plumbi subac., gtt. x;
Vaseline, ℥ii. M.

Fiat unguent.

Sig.—Apply before going to bed.

During the day such patients ought to use a solution of alum and camphorated water:

℞ Alum., gr. x;
Aq. laurocerasi, f℥ss;
Aq. camphoræ, f℥j. M.

Sig.—Use as an eye-lotion three times a day.

One word with regard to the hygienic management of patients suffering from blepharadenitis and eczema of the lids. Such patients should not be kept in badly-ventilated rooms. Their bedrooms especially should be light and have good ventilation. They ought to have as much out-door exercise as possible, and their general condition ought to be faithfully attended to. You will find in most of these cases that their diet has been sadly neglected by the parents. You should insist that the child have only three meals a day, nothing whatever between meals. Sweets and pastry, such as pies, etc., ought not to be allowed. The child ought not even to have bread or crackers between meals. The following mixture, which varies a little from the officinal, may be given with advantage:

℞ Sodii bicarb., ℥ij;
Fl. ext. rhei, f℥ij;
Ess. menth. pip.,
Ess. zingib., āā f℥j;
Aquæ ad f℥iv. M.

Sig.—For a child, a teaspoonful three times a day; for an adult, a tablespoonful three times a day, half an hour before meals, diluted in sufficient water to make it pleasant to take.

There is another form of blepharadenitis, accompanied by thickening of the free edge of the lid. This thickening can be best relieved by the following application:

℞ Ungt. hydrarg. nitr., ℥ss;
Ungt. simpl., ℥iij. M.

Fiat unguent.

Sig.—Apply morning and evening.

I have spoken also of another—the squamous—form of blepharadenitis. Here it is absolutely necessary to correct any error of refraction which may exist. The adjustment of glasses for such patients is fully as important as any local remedies which you may resort to. You will find that cases of this kind, in which the disease has existed perhaps for years, will rapidly improve after proper glasses shall have been prescribed. I have also found of great value in these cases a stimulating lotion composed as follows:

℞ Spir. vini gallici,
Spir. lavand. simpl., āā f℥ss;
Spir. rosmar. simpl., f℥iij. M.

Sig.—Apply to the lids morning and evening.

Do not forget to tell the patient that when applying this lotion to the lids the eye should be tightly closed. If, however, any of it should get into the eye, it will cause considerable smarting; but it will do no harm. If you will tell your patient to allow a few drops to evaporate from the palms of the hands, holding the hands up to the eyes, opening and closing the eyelids so as to allow the vapors to come in contact with the free edge of the lids very thoroughly, it will produce a better effect.

In those cases of inflammation of the free edge of the lid where there is a certain amount of redness remaining, all active inflammatory process, however, having subsided, a preparation of the following kind will have a good effect:

℞ Ol. cadini, gtt. v;
Ungt. simpl., ℥j. M.
Fiat unguent.

Sig.—Apply at night.

All these ointments should be used at night. If it be applied to the free edge of the lid during the day, some of the grease is very apt to get into the eye and produce slight disturbance of vision. The ointment should therefore be cleaned off the lid the next morning by washing with water containing a little bicarbonate of soda or Castile soap.

You will occasionally meet with very chronic cases of eczema of the lid, and in these cases it may be necessary, especially in adults, to give arsenic. For this purpose you may employ either Pearson's or Fowler's solution. If you do not wish to tell your patient to use simply so many drops of Fowler's solution, a very nice vehicle will be found in syrup of ginger:

℞ Liq. potassii arsen., f℥iss;
Syrupi zingiber., f℥iij. M.

Sig.—One teaspoonful three times a day after meals. For children the amount of arsenic should be diminished, one minim three times a day being sufficient.

It is hardly necessary to tell you, gentlemen, that in children of a scrofulous constitution you should give cod-liver oil combined with the iodide of iron:

℞ Syr. ferri iodidi, f℥ss;
Ol. morrhuæ, f℥iv;
Syr. zingiber., f℥ij. M.

Sig.—A half to one teaspoonful three times a day.

If this be well shaken, the cod-liver oil will be found to be very much disguised by the ginger syrup.

Where there is much of an eczematous condition, with an abundant formation of yellow crusts, I have found calcined magnesia with rhubarb of great service:

℞ Magn. cal. pond., ℥iss;
Fl. ext. rhei, f℥ii;
Ess. zingib., f℥ss;
Aq. anisi, f℥iv. M.

Sig.—One drachm three times a day before meals.

Some cases of blepharadenitis are due to traumatism, but usually in these cases the injury to the lid is comparatively insignificant, the injury to the eye being, as a rule, of greater importance. Among injuries of the lids are burns, and these are treated with great advantage with a weak solution of creasote:

℞ Creasoti, gtt. v;
Aquæ, f℥iv. M.

Sig.—Apply to the eyelid.

If the burn affect the eyeball as well as the free edge of the lid, it will be necessary to prevent adhesion of the edge of the lid to the eyeball (symblepharon). The use of a preparation which contains a very thick oil—such, for instance, as castor oil—is of special service.

In most cases the cornea is also affected, and for this reason I combine castor oil with atropine. As it is necessary to have the oil in its purity, not mixed with water, the solution should be prepared in the following manner:

℞ Atropinæ puræ, gr. ij;
Ol. ricini, f℥j. M.

Sig.—Apply one drop to the eye every hour.

The druggist should not dissolve the atropine in a few drops of water and then mix with the oil, because in this case the effect of the oil would not be as great as if it were free from water. The atropine should be dissolved in a few drops of alcohol, and then mixed with the oil, and then the whole slightly warmed so as to have all the alcohol evaporated. In that case you get a perfectly clear solution of the atropia in the castor oil. If this be applied, say one drop every fifteen minutes or half-hour, not only will the burn of the free edge of the lid be speedily relieved, but the formation of symblepharon will also be prevented.

One of the sequelæ of blepharadenitis is extension of the process to the hair-follicle and subsequent loss of the eyelashes. This occurs sometimes quite early in the disease, and at other times it is only towards the latter stage of the affection that the eyelashes begin to fall out. As long as only a limited number are lost, it is not a serious affection; but if it occur later on, as a result of cicatrization of the free edge of the lid, all the hair-bulbs may be destroyed, and the deformity, known as *madarosis*, will be very great. It is therefore important to attack the inflammation at the edge of the lid as early as possible. The very fact that we are using for the treatment of the disease the oxide of mercury will cause stimulation of the parts and prevent loss of the eyelashes, to a certain extent. After the disease has been relieved, and the eyelashes do not grow rapidly, the stimulating lotion of lavender and rosemary which I have mentioned will act very beneficially. In fact, the use of this after the disease has been relieved will be of great service in preventing a relapse of the trouble, not only because of its stimulating action, but because it dissolves the grease which might possibly be stopping up the mouths of the glands and thus causing irritation.

I was speaking of blepharadenitis due to errors of refraction. This is really of more frequent occurrence than we formerly had any idea of. The credit for calling attention to this fact is principally due to Dr. St. John B. Roosa. During the Ophthalmological Congress which was held in this city, he read an elaborate paper on this subject, showing by numerous cases the relation between errors of refraction and obstinate blepharadenitis. At this time it was doubted very much by our English confrères, but at present the cause is universally accepted. It is, however, unfortunate that only very few of the text-books mention it. Of course it is always comparatively easy to recognize this cause, but it is not always so easy to remove it. The patients are not always willing to wear glasses; it may interfere with their business, or it may be that they cannot pay for the cylindrical glasses which are necessary for the correction of these eye-troubles. In such cases I have recently used, in conjunction with the other remedies mentioned, a weak solution of atropine, dropped into the eye morning and evening:

℞ Atrop. sulph., gr. j;
Acidi borici, gr. x;
Aquæ, f℥j. M.

Sig.—One drop into the eye morning and evening.

I have been led to the adoption of this plan of treatment by the fact that patients who had been suffering from blepharadenitis for a long time, error of refraction being the principal cause, and being placed under the influence of atropine in order to make out the error of refraction, would get entirely well of the blepharadenitis within a few days. Of course it is evident to you how this remedy acts: it paralyzes the power of accommodation; it does away with all straining of the eye fully as effectually as correcting glasses would do. In a great many cases, if the disease be cured once, and the patients are a little careful with regard to the use of their eyes, no relapse will occur, even if they do not wear glasses for the correction of the error in refraction which exists.

PARALDEHYDE MIXTURE.—In order to overcome the rather disagreeable taste of paraldehyde, many corrigents have been suggested. Sutter recommends the following:

Paraldehyde, 10;
Rum (Jamaica), 15 to 20;
Spts. limonis (recent), 1;
Syrupus, 30;
Aqua, 139 to 144. M.

Dose is 100 gm., or a small wineglassful.

Ivon gives this formula:

Paraldehyde, 10;
Alcohol at 90°, 40;
Tr. vanilla, 2;
Aqua, 30;
Syr. simplex, 60. M.

Dose, f℥j to f℥ij.

ORIGINAL COMMUNICATIONS.

SOME COMPARATIVE RESULTS OF TREATMENT IN CHRONIC OSTITIS OF THE HIP.

BY V. P. GIBNEY, A.M., M.D.,

New York.

Read before the American Academy of Medicine at its Annual Meeting, Baltimore, Maryland, October 29, 1884.

TOWARDS the close of the present summer there came under my observation two cases of convalescent ostitis of the hip, which strengthened my conviction that there was much more to be expected from a patient management of these cases based upon a rational pathology than from the employment of any special splint, however highly recommended. And when I was invited so courteously to contribute something to this meeting, I gladly availed myself of the opportunity of talking to a body of men who are not carried away by sentiment and an uneducated enthusiasm, but who come to the study of a subject with a scientific habit,—men who by their very educational training demand facts, and arguments constructed thereupon, for conviction.

These two cases, I say, are to furnish me a theme for the present occasion, and with this theme I propose to illustrate by clinical memoranda some of the results men obtain in every-day life.

Let me premise, however, the statement that what we call "hip-disease," "hip-joint disease," "morbus coxarius," "coxalgia," etc., I prefer to call, for reasons both pathological and therapeutical, *chronic ostitis of the hip*, or *chronic articular ostitis of the hip*. The former perhaps expresses quite as forcibly as does the latter the idea I want my hearers and my readers to entertain of the disease now presented for discussion. The time has already come when a diagnosis can be made of early primary bone-disease, and with the symptoms and the signs of the same it is not my purpose on the present occasion to deal.

Let me preface further my remarks, in order to give a clearer understanding of the subject, with a list of the various therapeutical measures in vogue.

I.—THE EXPECTANT METHOD.

I have not qualified the term "expectant," strong though the temptation be, by a "so-called," or "as it is commonly understood," for the reason that I desire to let the method go by the name its advocates prefer. What we understand by the expectant treatment is a treatment that consists of (*a*) a good hygiene, coupled with the internal administration of drugs supposed to arrest or to change a constitutional vice, known as a diathesis, either hereditary or acquired, commonly called struma or scrofula; (*b*) counter-irritation by means of issues, the cautery, or vesicants more or less severe; (*c*) liniments and the roller in the shape of a spica bandage, compresses of cotton batting often being placed over areas of fulness; (*d*) the non-interference with abscesses until acumination takes place, and then the making of a simple punctured wound through an abnormally thin integument; (*e*) the complete rejection of apparatus of any kind to prevent or correct deformity until one can feel satisfied that the morbid process is arrested; (*f*) intermittent force of an elastic nature, the object of which is to correct deformity that has become fully established.

A long residence in a hospital unalterably committed to this treatment enables me to define thus minutely the method known as expectant. I am pretty sure that I do not convey an erroneous impression.

What I have elsewhere defined as the expectant treatment carried to its legitimate issue differs materially from the present definition.

What then are we to expect in a given case subjected to this plan? Scientifically, what can we expect from a course of treatment which ignores all contrivances for the prevention of deformity?

Even the stanchest advocates of the expectant treatment in ostitis of the hip inconsistently employ apparatus for the prevention and correction of deformity when other joints of far less importance than the hip-joint are endangered by contagious disease.

Next in order comes the

II.—CONFINEMENT TO BED WITH WEIGHT AND PULLEY.

This is the old plan, and has much to commend it, although much more to condemn it. It has the advantage over the expectant plan of not bringing the whole weight of the body on a diseased femoral neck. If we can accept the postulate,

that the lesion is a rarefying ostitis in and about the centres of development, and that this rarefying ostitis, as a rule, terminates in caseous degeneration, we must guard against throwing any weight on this portion of the femur. It must be remembered, too, that in walking upon a limb either really or apparently shortened, the weight of the body is thrown upon this limb at a great disadvantage. We are all familiar with the thud-like step of a hip-limp. Is it any wonder that the trochanter sooner or later appears above Nélaton's line?

It is well known that the weight and pulley, in conjunction with the inclined plane, forms the preparatory treatment to the splint, if much deformity exist. A few weeks usually suffice, and then the long splint can generally be worn with more ease.

III.—THE AMERICAN METHOD.

This has been given the name by our transatlantic brethren, and is known as that plan which aims at portable extension with motion. The weight is thrown upon the perineum, and the splint is practically a perineal crutch. American orthopædists, with few exceptions, aim at producing sufficient traction to prevent any shortening or osseous deformity, and at the same time to preserve the motion at the joint.* Just how well this last aim is realized, we are in need of cases and statistics to state with anything like positiveness. I have no hesitation in classing myself among those who believe that any motion permitted a joint whose bones enter into its mechanism only procrastinates the treatment and militates seriously against any proper preservation of function.

IV.—FIXATION OF AND REST TO THE JOINT.

The appliances that have this end in view are numerous, and may be enumerated in the order of efficiency: 1. The "physiological plan," as advocated by Dr. Hutchison, of Brooklyn. This is well known as a high shoe on the foot of a sound limb, and a pair of axillary crutches. The limb is thus raised from the floor and swings, while the weight of the body is thrown on the axillæ. The reflex spasm of the periarticular muscles is sufficient, it is claimed, to fix the joint. Were the patient continuously on the crutches, the indications might thus be fairly met. At night, however, the weight and pulley are used. 2. Apparatus made to encase the hip and thigh, and used in conjunction with the axillary crutches and high shoe. This appliance consists of plaster of Paris, felt, leather, gauze, etc. 3. The long and the short extension-splints, with their various modifications. All these splints are secured by means of adhesive plaster to the limb, by means of which traction is made, and perineal bands fastened to a pelvic band. In reality the hip and the knee are fixed, while the patient walks on the perineum instead of the diseased limb. 4. The splint employed by Hugh Owen Thomas, Esq., of Liverpool, which aims at immobilizing the spinal column, the hip, and the knee, is more in accord with the principles advocated. This splint is incomplete without the crutches and the high shoe. Cumbersome as this apparatus appears to be from the published accounts of the same, I am convinced that a certain class of patients are better protected and get about more easily with such an outfit than we imagine. Let a patient once feel assured that his limb cannot get out of position, and that he can go about with immunity from injury, and he will accustom himself to almost anything. Through the courtesy of Mr. Thomas, I have had an opportunity of seeing some of his patients while under treatment, and they certainly seem contented and get about very actively.

Whether we in this country, satisfied as we are with the use of our portable perineal-crutch splints, will ever consent to fixing the spinal column as well, and to substituting the perineal for the axillary crutch, I have grave doubts. Indeed, I am quite sure that cases managed with the same assiduity that Mr. Thomas gives to his cases will terminate quite as successfully.

V.—OPERATIVE PROCEDURES.

The forcible correction of deformities under an anæsthetic, osteotomies, and excisions constitute the surgical means employed, but means such as these must be supplemented by apparatus in order to retain the advantage gained. Under osteotomies I wish to be understood as including linear osteotomy, drilling, and ignipuncture.

In the remarks I shall make by way of clinical illustration, I shall say nothing of the operative procedures. The subject of

excision is so hackneyed that little good can come out of a discussion. All thinking men are agreed upon its value as a *dernier ressort*, and, when otherwise employed, men differ, and will differ, according to individual experience and the value they attach to statistics.

Touching *brisement forcé*, as a means of correcting a bad flexion for instance, much diversity of opinion exists. The more conservative of orthopædic surgeons do not prefer this to gradual extension; in fact, it is strongly condemned. So far as my own experience goes, I am not a strong advocate of this plan. When one wishes to save time, and can feel reasonably sure of not aggravating or lighting up afresh a bone-lesion, then it may be done. Ordinarily, however, it is much safer, and consequently more commendable, to resort to gradual processes.

The theories upon which simple linear osteotomies and ignipuncture are based make these operations eminently justifiable.

Patients, as a rule, outside of hospitals are loath to submit to operations of this nature, and the results thus far published are not sufficiently reassuring to give one a strong argument for appeal to the lay mind. The pathology as yet rests on too insecure a basis. Men still talk about "distention of the capsule," "erosion of cartilage," "extension of the inflammatory process to the bone," and such-like theories of a bygone day, as if they were facts. The professional mind is not yet educated up to a sound pathology.

Drilling of the head and neck has not been employed always on properly selected cases, and the results therefore give one an unfair impression. Diagnostic skill has not been brought to bear with sufficient force. However one may favor this method of dealing with an early ostitis, for many reasons it seems doubtful whether it will ever become a popular operation. Elsewhere I have published some results furnished by my friend Mr. C. McNamara, of London.

For results of osteotomy for the correction of bad positions, I cannot do better than refer to the valuable work of my friend Dr. C. T. Poore on "Osteotomy and Osteoclasis," published by the Appletons.

To illustrate some of the results gained under the different methods non-operative, I shall incorporate a few brief notes of cases taken from my records.

(*A*) A young lady is now under my observation who has from the beginning of her lameness, many years ago, been under expectant treatment. She is in fair health, and is able to walk with much ease when not harassed by neuralgic pains,—a sequel to her ostitis. There is anchylosis at an angle of about 150°,—a comparatively good result as to position,—while the amount of adduction is not by any means great. There is only one inch shortening. Over the trochanter major is an open sinus, which to my own knowledge has been in existence for five or six years. The discharge is not profuse; on the contrary, it is scarcely sufficient to require at all times a dressing. What annoys the patient most is an almost constant pain in the outer portion of the thigh and around the knee. This pain, too, is aggravated by walking. But for this annoying feature and the pertinaciousness of the sinus, the result would be one better than the average.

Take now a case treated after the same plan nearly forty years ago. One year ago I had under treatment for fibrous anchylosis of the hip the following case:

(*B*) A man, 47 years of age, who gave me this history. When quite a lad, he had a disease at the hip, and was treated by blistering and occasional periods of rest. He was nearly a year an invalid,—was "laid up off and on." He never had any abscess, and gradually "the disease wore away," but the hip has always remained stiff. It never troubled him to any great extent, however, until 1880, when, from exposure he thinks, he began to walk with less facility. Finally, he became so lame and suffered so much pain about his hip that he sought relief in a hospital. Failing to get the desired relief, he tried other hospitals. When I examined him, I found only an inch shortening, with the usual amount of thigh-atrophy,—viz., two inches. The limb was rotated outwards over an arc of about twenty degrees, and he walked exactly like one who was convalescing from fracture of the femoral neck. He could flex the hip to an angle of 120° with a little effort, and, on extending from this position, he rotated the limb outwards, the act of extension being accomplished by a slipping of the head over a roughened surface. This movement I had him repeat several times, as it was to me a very odd "trick" on the part of the patient.

In seeking a solution, I could come to no other conclusion than this,—viz., that in flexing the thigh he must produce a subluxation of the hip downwards and backwards, which subluxation was overcome with this "click," or bony slipping, on extending the limb.

These movements did not excite any special pain, but walking and climbing stairs did excite pain, and altogether he was a great sufferer.

It occurred to me, after exhausting counter-irritants and the various forms of electricity, that relief might be afforded by freeing the hip of what adhesions might exist in this locality. Accordingly, I moved the hip one day, under an anæsthetic, to 90° in flexion and 170° in extension, but was unable to make any abduction or rotation. He did not get any near or remote relief from this operation. He was made worse.

Occasionally one meets with old cases that have been subjected to issues during the progress of the disease.

(*C*) In June of the present year a case was referred to me for advice regarding the best means of controlling a pain in the gluteal region. The patient was 28, and when five years of age had developed ostitis of the hip, for which she came under the care of distinguished surgeons. Issues were employed, cicatrices of which I found in the gluteal region. One of the issues existed for two years. No splints were ever used. Her treatment extended over a period of three years, but it was five years before she was regarded as cured.

From her tenth year until December, 1883, she had no relapses, and scarcely any symptoms that could be regarded as evidences of an exacerbation.

Last December she was unusually active, and, after a hard day's work in household matters, suffered excessively about the hip for a couple of days. A few days' rest in bed brought about relief, and her chief annoyance since that time has been her inability to walk moderately short distances without exciting pain in the gluteal region. She grows weary very quickly.

Her physical condition now is: a good physique; a marked lumbar lordosis; a thigh flexed at 135°,—*i.e.*, on overcoming the lordosis; two and a quarter inches shortening as measured from the anterior-superior spinous process; one and three-quarter inches shortening as measured from the umbilicus; two inches atrophy of the thigh; no joint-tenderness, and a very fair gait. Altogether, the result, for an anchylosed hip, is very good, and, but for the periarticular sensitiveness, would be all that one could expect.

These cases afford practical illustration of the kind of hips one may get by the old method of treatment. I regret to say that these are selected cases. I should like to tell of a case referred to me yesterday by the head of a noble charity:

(*D*) A little girl, flaxen-haired and wan, I found seated in the well-known high chair around which so many loving memories of our childhood fasten themselves, steadying herself as best she could by the foot-board and the arms of the same. Thus seated in apparent comfort, she scarcely seemed the patient I had been called to see. But could you have heard the piercing, the agonizing shrieks that issued from this frail human specimen as the mother took her into her arms, could you have seen the haste with which she grasped the knee with both hands, could you have seen how tearfully she resisted any attempts at moving either limb, could you have seen how acutely flexed both thighs were held, you would not believe me if I told you that this case developed disease of both hips directly under the surgeon's eye and while under treatment for lumbar caries, and that the signs of bone-disease at the hips developed slowly and according to rule.

This is not an isolated case. I could make a lengthy paper with the transcription of similar records. The time has passed when we can afford to disregard the appliances science has thrown into our way.

Take now, by way of illustration, a few instances wherein the long splint has been used:

(*E*) A boy, 14 years of age, was seen after three years' treatment, with this result: The health excellent; no pain for a year or more; six open sinuses, but the discharge therefrom is very light; the limbs are parallel, there is no shortening, and the patient walks with ease, although a little lame. The limb has been retained in good position, and no shortening has been allowed, while at the same time he has been walking all the while. These open sinuses give the doctor very little anxiety, and the boy has come to look upon them as of trifling import. The fact is that sinuses leading to carious bones may exist for several years without any grave significance. Very often they finally close permanently.

Cases come under observation, and histories are given, of treatment such as the general surgeon employs,—viz., a combination of the weight and pulley and portable apparatus. The text-books on surgery commend in strong terms this combination.

(*F*) In August a patient was referred to me from Kansas City by a gentleman who ranks high as a surgeon, and in his letter he remarked that during the progress of treatment he thought the result would be exceptionally good as to motion and freedom from shorten-

ing. This is what he did. Two years and a half ago, three months after the first signs of disease in the hip, he applied a long splint. The patient wore this awhile, then had weight and pulley in bed, then the splint again. Later an abscess formed, but this was treated according to surgical principles.

This is the result:

A well-nourished, hearty-looking girl, 8 years of age, on a crutch, with one and a quarter inches real shortening of the limb and three and a half inches practical shortening. The top of trochanter major is one inch above Nélaton's line; the angle at which it is possible to extend the thigh is 125°, to flex 75°. The usual amount of atrophy exists. A cicatrix on the upper and outer aspect of the thigh marks the site of the abscess. The disease seems fully arrested, and the child can walk on the limb, but has become attached to the crutch, and it is hard to make her abandon this aid in walking.

In July I saw a patient from Cincinnati, Ohio, with the following therapeutical history:

(*G*) Two years ago, very soon after the first signs of an ostitis of the hip developed, a Taylor's long splint was applied, and this she wore three weeks. It gave place to the weight and pulley, which was continued for fifteen months. Towards the close of this period an abscess formed and was opened, a sinus continuing eight months. In this time she wore a plaster-of-Paris bandage for three weeks. Since the removal of the plaster she has been on crutches.

The outcome of the above treatment is: She keeps the thigh flexed on the pelvis at an angle of 80°, making the practical shortening of the limb two and one-half inches, while there is no shortening as measured from the anterior-superior spines, the limbs placed symmetrically. There is also a marked degree of adduction, and a deep cicatrix on the outer side of the thigh. The joint-surfaces seem smooth, and there is a small arc of motion in all directions. Passive motion excites reflex spasm in the adductors, which spasm indicates that the disease is not yet fully arrested.

Now, these two cases represent very fairly the average result of bone disease about the hip when managed, as the case usually is, by two or more surgeons. And yet, as time goes on, they will walk with a much improved gait.

To show the termination of some cases that are under the care of orthopædic surgeons who differ as to methods of treatment, a brief narration of the history of a patient I saw first in 1882, while an interne of the Hospital for the Ruptured and Crippled, will suffice:

(*H*) The girl was then 15 years of age, and had worn a long hip-splint, applied by an accomplished specialist, for three years. The limb was parallel with its fellow, was one inch short, but the dropping of the pelvis on this side reduced the practical shortening to nil. There was no atrophy of the limb, no abscess, and the disease, although of long standing, seemed to be undergoing resolution. Coming to the hospital, she naturally had to give up the splint, and took to crutches, inasmuch as she was afraid to risk the limb alone.

From June, 1882, to February, 1884, the "expectant" treatment was pursued, and at the end of that time she had, as a result, one and a half inches real shortening, one inch practical shortening, an inch and a half atrophy, inability to walk without the crutches, and a stiff hip in the straight position.

In February she entered the New York Hospital for the purpose of having an operation done for the relief of the anchylosis. The hip was quite freely moved under ether, and the weight and pulley employed for six weeks, passive motion without an anæsthetic being employed occasionally during that time.

Since June I have had her under observation, using the long splint again, and with this she gets about without other aid. The *brisement forcé* in February has been attended with negative results.

To sum up, then, the points of interest in this case: 1. Long splint for three years employed by an expert. 2. Treatment by crutches and liniments for eighteen months at an orthopædic hospital. 3. *Brisement forcé* at a general hospital. 4. Long splint again. 5. A strong probability that she has five or six years of splint-treatment yet in store.

However prejudiced one may be against mechanical treatment, he cannot escape the conviction that had this case continued the long splint awhile longer, progressing favorably as it was, a good result would the sooner have taken place.

Little is heard now of the physiological treatment so ably advocated by Dr. Hutchison, of Brooklyn, a few years ago. My own results have not been such as to encourage me to hope for any great success.

(*I*) Recently I have examined a little patient with whom I began the crutch-and-high-shoe treatment fully three years ago. I had the case under observation quite closely, and the directions have been followed with precision. When the plan was adopted the case

had already reached the second stage. Six months afterwards an abscess appeared in the iliac fossa, and was distinctly made out by myself. Six months later it had disappeared. This child had very little pain during the whole course of treatment.

The condition now is, a comparatively easy gait without pain, one and a half inches shortening as measured from the anterior-superior spinous process, and four inches as measured from the umbilicus (four inches practical shortening). Can flex quite as freely and quite as fully on this side as on the sound side, while extension is limited to 120°.

This, you see, is not a fine result; and yet I am compelled to bring it forward as one of my best, if not the best of any yet obtained by means of the "Physiological Method."

To Mr. Hugh Owen Thomas, of Liverpool, I am indebted for the opportunity of examining a sample case under his care.

(*J*) One day early in September a child was brought to my office with a note from Mr. Thomas. I soon learned this history.

About three years ago I had examined the case, when it was in its incipiency, pronouncing a diagnosis without hesitation. I did not see it again, but the child was taken to Dal Cin, the bone-setter, in her Italian home. Here she remained nine months, getting poultices and an occasional stretching. Thence to Liverpool, where the case came under the care of Mr. Thomas, who has had it under his personal observation for two years, with this result:

A very active child, still wearing the fixation-splint employed by Mr. Thomas, supplemented by a three-inch high shoe on the sound foot and a pair of crutches; the limb parallel with its fellow, one inch shorter and one and a half inches smaller; the joint apparently anchylosed. There was no soreness or pain, and a cure seemed long since attained.

We had here a straight limb, a short limb, and a stiff joint. Curiously enough, three days later, another case was brought me for my opinion as to the propriety of suspending all treatment, and this was the coincidence:

(*K*) The family-name of the child was the same as the one whose case I have just reported. The disease began about three years ago. I had seen the child and diagnosticated the lesion early, and had not had the opportunity of treating the same. This child was taken to an orthopædic establishment in a neighboring city, where she was placed in bed with a weight and pulley attached to the limb, and here she lay for sixteen months. At the end of this period crutches and a high shoe were employed for six months. The result is almost identical with that in the Liverpool case as to position, atrophy, shortening, and stiffness.

Both were good, yet far from perfect. In both treatment was begun comparatively early, both were managed with much care, and both reflect credit on the surgeons in charge.

In studying comparative results, I am forced to the expression of the following convictions:

1. The "expectant" treatment is not, in an orthopædic or a surgical sense, any treatment at all. Cases that have no medical or surgical attendance whatever are followed, so far as my own observation goes, with just as good results.

2. Traction with motion is based upon a false pathology, and does not, in my opinion, do what its advocates claim for it. The motion is certainly not as great, as a rule, as one would be led to expect.

3. Fixation and rest, when properly carried out, yield better results, I believe, than any other plan.

4. The key-note in the treatment of ostitis of the hip is not the splint employed, not the crutch, or the high shoe, but it is the management of the case. Some men can get admirable results with any kind of splint. The case must be closely watched, the apparatus must be kept fully up to its duty, the indications must be met, and one must not grow impatient, because time is an important factor.

Let one be early impressed with the tediousness of the case, and let him also make up his mind that the case must be managed rather than treated with any special form of apparatus.

REPORT ON OPHTHALMOLOGY.

BY ALBERT G. HEYL, M.D.,

Ophthalmic Surgeon to the Episcopal Hospital.

BRAIN-ABSCESS WITH DOUBLE OPTIC NEURITIS.

DR. GEORGE S. NORTON reports the following case. William H., æt. 22, received a blow on the head from an ice-hook. For two weeks he was confined to the house, part of the time in bed. He seemed, however, to recover

from the effects of the blow, but one and a half years later began to suffer from severe and almost constant headaches. A few months later he was obliged to stop work on account of a severe "cold and fever." In a few days the R. E. became very much swollen, as well as the corresponding side of the head. Then daily muscular spasms for nine days supervened. They ceased, but recurred again in about a month, lasting for three days. About this time blindness was noticed in the R. E.; paralysis of speech and also of the extremities occurred. L. E. became blind about five weeks after the blindness was first noticed in the R. E. Three weeks after this the convulsions returned. Examination at this time revealed the following: "Patient lies helpless in bed, only slight movements of either arms or legs being visible. Lower jaw is fallen, apparently from paralysis of the masseters. He seems rational, but is unable to speak. Practically blind in each eye. Much swelling of the lids of the R. E. Some chemosis of the conjunctiva, with prominence of the eyeball. Cornea in a state of suppuration. The right side of the head is much swollen and hard. At the edge of the orbit, near the outer canthus, is a fistula from which pus escapes. In the L. E. the pupil is widely dilated, the media are clear. There is a characteristic engorged papilla." About a week later patient became comatose and died.

The autopsy showed caries of the orbital plate of the frontal bone, corresponding to the apex of the lesser wing of the sphenoid, by means of which an opening had become established into the right orbit. A large closed sac of pus occupied the place of the right middle cerebral lobe, no trace of which remained.

[It is a question in the above case whether the carious bone was primarily affected by the injury or not. The pus-sac was in contact with, but not adherent to it; no communication existed between the former and the orbital cavity. These facts, together with the acute brawny swelling of the right side of the head, suggest the following explanation. The caries of the orbital plate was simply due to the pressure of the pus-sac; it seems not to have been accompanied by adhesive inflammation; possibly, therefore, the part which was played by the caries in the production of the orbital inflammation may have been very slight. The train of symptoms seems to point rather to a metastatic inflammation of a venous sinus, involving secondarily the ophthalmic vein and its branches, and also the veins of the diploic structure of the right side of the head; the veins of the diploë communicate both with the sinuses of the dura mater and with the pericranial veins. It is therefore not so difficult to explain the brawny swelling of the side of the head, a symptom, so far as the reviewer's experience goes, not usually associated with cases of orbital abscess. H.]

GLAUCOMA FROM HOMATROPINE.

Dr. Sachs reports the following case. The patient, a blacksmith, æt. 58, applied for a prescription for glasses. The anterior chambers were shallow, pupils of normal width. Tension also normal. The right lens was slightly cloudy, and in order to examine this more closely a drop of a one-per-cent. solution of homatropine was instilled. Fundus, visual field, and color-sense normal on each side. Twenty-six hours later he appeared, making the following complaint. Almost immediately after leaving the clinic, pain occurred in the right brow and temple, with decrease in sight. There was also the sensation of giddiness. The symptoms, however, were not severe enough to cause great annoyance to the patient. Examination showed that a typical glaucomatous affection of the R. E. existed. Cornea, especially the central part, steamy. Anterior chamber narrow to the same extent as before the instillation; pupil rigid and dilated to five and a half millimetres; fundus dimly seen, but the jumping arterial pulse of glaucoma was easily observed. Tension very much increased. Vision reduced to counting fingers at three metres. Visual field narrowed on the temporal side. Immediately several drops of one-per-cent. solution of eserine were instilled in the R. E. One hour later the glaucomatous symptoms had vanished; cornea was clear, pupil reduced to one and a half millimetres in diameter; tension less than that of the left eye. Vision in large measure returned. In two days, with further use of the eserine, the vision attained the amount existing before the instillation, and the visual field became normal in extent. The eserine was stopped. In course of six days the pupil was nearly as wide as that of the

L. E. The tension of R. E. still a little less than that of the L. E. The fundus was normal. Further examination of the patient drew out the fact that for four years he had experienced at times, especially when working hard, a dimness of sight which would last perhaps fifteen minutes; there would be also giddiness, but not the slightest ocular pain.—*Centralblatt f. Augenhlk.*, September, 1884.

[This case recalls again the practical lesson of using mydriatics with caution in patients over fifty years of age. The ill effects from atropia-instillation in glaucoma, the fact that acute glaucoma has been developed by duboisia,* and the above case produced by homatropine, may well lead us to suppose that, where the predisposition to glaucoma exists, *any* mydriatic may bring on an attack. It is an important practical question, in view of this, whether it is a wise thing to use a mydriatic in refraction cases over fifty years of age. This very case of homatropine glaucoma shows how impossible it is to determine from the condition of the eye itself whether the mydriatic may be used safely or not. The reviewer inclines to the belief that it is safer to be satisfied with the best correction that can be given without the mydriatic in such cases. In younger individuals the use of the mydriatic seems as yet indispensable. H.]

PEMPHIGUS OF THE CONJUNCTIVA.

Steffan, of Frankfort, reports the following instance of this rare affection. A woman, æt. 73, presented herself for treatment on account of an inflammation of the L. E. There was a moderate amount of conjunctival inflammation, with a peculiar cicatricial process running on in the inferior conjunctival sac. Some of the cilia of the lower lid were drawn inwards, thereby irritating the cornea. With continuance of the inflammation the inferior conjunctival sac became shallower, finally disappearing in the outer third. The cause of this cicatricial process could not then be discovered. There was no evidence of granular conjunctivitis. The condition was evidently that described by Gräfe as *essential shrinkage of the conjunctiva*, and by Stellwag as *syndesmitis degenerativa*. The R. E. then became inflamed, and the same cicatricial process began to develop in the inferior conjunctival sac. Finally scarce a trace of the sac remained, the lower lid being closely united to the ball. A month after the inception of the disease an eruption of typical pemphigus vesicles occurred, first on the left, then on the right eyelid. On the latter, during one and a half years' observation, the vesicles would come and go. There also occurred during this time an affection of the throat which was diagnosed as pharyngeal pemphigus. Steffan draws the conclusion from his case that this confessedly obscure condition of conjunctival shrinkage is really the result of a pemphigus eruption, and that the proper name for the condition is pemphigus conjunctivæ.—*Klin. Monatsblätter*, August, 1884.

Schweigger reports a case of the same kind. The patient was a robust old man. There was marked injection of the scleral conjunctiva of each eye, a partial shrinkage of the inferior palpebral conjunctiva, and disappearance of the inferior conjunctival sac, while the upper lids were healthy. A few months later a pemphigus vesicle developed itself on the right scleral conjunctiva. For years previous similar vesicles had been observed on the mucous membrane of the mouth.—*Centralblatt für Prakt. Augenheilkunde*, June, 1884.

ANOMALIES OF THE OPTIC DISK.

I. Coloboma.—Remak describes the following case. The patient was a woman æt. 26. Both eyes have optic disks of about the same diameter, and are slightly hypermetropic. The coloboma was in the R. E., the left optic disk being normal. The right disk was embraced by a grayish-white staphylomatous crescent situated to the nasal side, and including two-thirds of the disk-circumference between its horns. In the middle of the disk was a deep physiological excavation with a diameter about one-third that of the disk. The edge of the excavation was sharply defined; at the nasal side a shallow depression in the disk-surface communicated with the excavation, and also with a split in the nerve-tissue. This last extended to the margin of the disk. There was no other evidence of defective development in the eye. A list of eight papers bearing on the subject is appended to the history of this case.—*Centralblatt f. Prakt. Augenheilkunde*, August, 1884.

* Acute Glaucoma induced by Duboisia. Reported by Albert G. Heyl, M.D. Amer. Jour. Med. Sciences, April, 1882.

II. Malformation.—Stood reports two cases: (*a*) Patient was a woman, æt. 40. V. in each eye about normal. With the ophthalmoscope the left fundus was normal. On the right papilla a vertically-oval bluish-white spot was noticed close to the margin; its horizontal diameter was one-sixth to one-eighth that of the papilla. It was in the temporal half of the papilla. From its appearance it might readily have been taken for a cyst, but close examination showed it to be an excavation with an overhanging rim. Examination of field showed that a scotoma existed between the *blind spot* (Mariotte) and the fixation-point. There was scarcely any indication of the ordinary physiological excavation. (*b*) In this case an excavation similar to that described in the first patient was observed close to the temporal margin of each disk. The excavations were connected with large physiological cups occupying the temporal halves of the disks. In the R. E., some distance below the papilla, a well-marked choroidal coloboma was observed. In the L. E. the choroid was perfect, with the exception of slight pigment-maceration about the macula.

[Remak's case seems clearly due to defective closure of the fœtal cleft, as the depression connects with a fissure running to the nerve-margin. Stood's cases seem to have a different origin. That it was fœtal seems to be indicated by the coexistence of a choroidal coloboma in the second case. The evident isolation of the depression, in the first case, from the porus opticus points rather to some local disturbance of nutrition, by reason of which the level of the disk was caused to sink. The resemblance of these excavations to those seen in glaucoma is worthy of note. H.]

COLOBOMA OF THE MACULA LUTEA.

Remak observed the following case. Patient æt. 16. R. E. was myopic 3 D; otherwise normal. In the L. E. the macular region was occupied by a sharply-defined oval spot; its vertical diameter was 2 PD, its horizontal 3 PD. This area in spots was intensely white, in others covered with accumulations of pigment; several choroidal vessels were also observed upon it. A branch of the arteria retinæ superior ran across the spot through the pigment-accumulation. There was no trace of choroidal or iris coloboma in either eye. The vision of L. E. was much decreased, fingers being counted at twelve feet.—*Centralblatt f. Augenheilkunde*, September, 1884.

[The etiology of these cases is not as yet clear. The prevailing opinion is that advanced by Manz,—viz., that they are due to imperfect closure of the fœtal cleft. This is confessedly a doubtful hypothesis. It is perhaps impossible to reconcile these defects in the macular region with the position of the fœtal cleft,—viz., downward or downward and inward from the disk. Nor does the supposition that the ball rotates during gestation seem materially to strengthen the hypothesis. It seems to the reviewer that it is illogical to refer the various forms of congenital tissue-defects to the fœtal cleft, as if there must be necessarily some connection between them. Certainly these tissue-defects do not imply the previous existence of a congenital cleft, but rather that for some reason the tissue-formation has failed to attain its full growth. The cause may be sought in the defective state of the fœtal blood-vessels contiguous to the defective tissue. H.]

DETACHMENT OF THE UVEAL PIGMENT IN DIABETES MELLITUS.

Hirschberg reports the following experience. A woman, æt. 54, with double cataract associated with diabetes mellitus, had a preparatory iridectomy made on the R. E. Operation was performed without difficulty, and there was no posterior synechia. Almost the entire pigmentary layer of the portion of iris removed remained behind. Five days later a preparatory iridectomy was made on the L. E., with the same experience. The pigment-layer was removed by the forceps. Hirschberg states that among hundreds of iridectomies he has observed this phenomenon but once, and then in an anæmic girl who had lamellar cataract.—*Centralblatt f. Augenheilkunde*, June, 1884.

[This clinical experience may be taken in connection with the observation of Becker made on a young girl, who died of diabetic coma two days after preliminary iridectomy on one eye and extraction on the other. The uveal pigment-cells were found very greatly swollen and loosened. H.]

PERIMETERS.

Dr. Dubois-Reymond describes a new

perimeter for testing the visual field. The main advantages ascribed to the instrument are absence of complicated mechanism and cheapness of price. It has the arc and chin-rest of the instrument of Förster, but the movable test-object is superseded by an object on the end of a blackened staff held in the hand and moved along the arc. The maker is Hr. Mechaniker Pfeil, Dorotheen Strasse 35, Berlin. The price is forty-six marks.—*Centralblatt f. Augenheilkunde*, September, 1884.

Dr. B. Alexander Randall, of this city, has recently devised a perimeter consisting of a brass arc backed with iron and an adjustable chin-rest, mounted upon a base of oak. The object is moved along the arc by an endless cord worked by a milled head near the centre of rotation. It seems to be much lighter than the heavy German instruments, and to fulfil the same purpose. The cost is ten dollars; the manufacturer, Mr. Ivan Fox, 1635 Chestnut Street, Philadelphia.—*Medical News*, October 11, 1884.

Priestley Smith describes a new, self-registering perimeter. It is an improved form of the instrument previously devised by him.—*Centralblatt f. Augenheilkunde*, June, 1884.

ELECTRIC LAMP FOR OPHTHALMOSCOPIC WORK.

Birnbacher describes an illuminating apparatus specially adapted for ophthalmoscopic work at the bedside. It consists of a Swan lamp enclosed in a cubical casket of forty millimetres' dimensions. The front face of the cube is open, and has connected with it a tube thirty-five millimetres in diameter and twenty millimetres long. Sliding upon this is another short tube, which has a convex lens set in it; the latter can thus be moved toward or away from the lamp, and thus parallel, convergent, or divergent rays caused to issue from it, as may be desired. The electric current is applied by a small and compact battery of six "Faure-Sellon-Volkmar" accumulators. Thus the light may be maintained for two hours at a time. The lamp may be also used for microscopic work, the light being tempered by a blue glass in front of the lamp. It also may be used at the operation-table when artificial illumination may be required.—*Centralblatt f. Augenheilkunde*, June, 1884.

REPORT OF A CASE OF ACCIDENTAL HEMORRHAGE COMPLICATED WITH RIGID OS, RESULTING IN THE DEATH OF MOTHER AND CHILD.

BY G. MAXWELL CHRISTINE, A.M., M.D.,
Philadelphia.

THROUGH the courtesy of Dr. J. D. Nash, the physician in charge, I have received permission to present the following account of a remarkable case. In a glance over many medical works, I have been unable to find anything like it, and there are probably few physicians who have had cases presenting similar features.

On September 8, Dr. Nash was summoned to Mrs. G., primipara, believed to be in the seventh month of her pregnancy. She stated that during the latter weeks of her pregnancy there had been some œdema of both legs, but this now gave her no unusual annoyance. For some hours the patient had suffered from intense pains attending a severe attack of diarrhœa. She was much prostrated; her face was pale and her pulse weak; but there were no signs present of labor. Under appropriate treatment the pains were relieved and the diarrhœa checked. For the next week she was enabled to go about her household duties, and those who saw her state that nothing unusual marked her appearance except pallor; but on the 14th, at about 2 P.M., the doctor was again summoned to Mrs. G., who had then been in labor for some hours. He was at once struck by her marked pallor and the weakness and rapidity of her pulse. Pains were occurring every five minutes. The appearance of the bed and the cloths which had been used showed that there had been a considerable loss of blood, and examination revealed that there was still slight bleeding. The os was high up, looking to the left, narrow, and exceedingly rigid, particularly during a pain. It was neither dilated nor dilatable, and the doctor very truly said that "nothing had ever so reminded him of a button-hole as that os." The opening was surrounded by a tough, unyielding, ring-like ridge, which was like the edge of a coarsely-made button-hole. The index finger could be introduced with much difficulty through this narrow slit up to the second joint, but it always gave rise to much pain and strong uterine contractions. The membranes she thought had been ruptured, but what had been supposed by the patient to be a breaking of the bag of waters must have been a gush of blood. The head could be felt quite high up, and during a pain made some movement as if to descend. The hemorrhage suggesting placenta prævia, the finger was swept around within the os to discover the presence

of the same, but there was no placenta within reach.

No correct estimate can be given of the amount of hemorrhage, but, judging from the fact that there had been a continual flow, with an occasional gush, for some hours before the doctor was called, the loss must have been great. The wasting now was not alarming, and the finger kept within the os easily checked it. But after retaining the forefinger within the os as a tampon for an hour, finding no change taking place in the condition of the os, and that a second finger could not be admitted, the doctor, at about three o'clock, determined to replace the use of the finger by a tampon of cotton and meanwhile call in assistance; but in half an hour so much blood was found to have oozed through that the tampon was removed.

After much manipulation a second finger was now partially inserted. The two fingers now effectually closed up the os, and served admirably as a tampon. They were therefore retained in this position for three-quarters of an hour, an effort all the while being made to dilate the os enough to admit a third finger. At the end of that time, finding his efforts to pass in another finger ineffectual, and that his fingers had become temporarily paralyzed from the constant pressure kept up, the doctor was obliged to desist.

It was at this time that I arrived. Dr. Nash hurriedly reviewed the case and requested me to make an examination. I found that there was still hemorrhage, but not very abundant. The os looked backwards and to the left, and was a little difficult to reach. It presented the button-hole character as described, but had evidently contracted after the doctor removed his two fingers, for I could insert but one. The membranes were intact, and the head was still high up. Pains occurred every four or five minutes, at which times the os would contract very forcibly, but it was very evident that they were having no effect in dilating the os. At last, after tugging at the os for many minutes, I succeeded in partially inserting a second finger. The membranes now slightly bulged during a pain, and, as the hemorrhage still continued unless controlled by a tampon or by the fingers, I ruptured them. There was but a slight escape of water, and this appeared to be unmixed with blood. We hoped, after the rupture of the membranes, that the head would further descend and fill up the os; but this did not take place, and some bleeding continued.

Belladonna ointment was now plentifully smeared upon the os, and the use of the fingers as dilators still persevered in; but no immediate effect was secured. In order to give the belladonna time to act, and meanwhile continue the control of the hemorrhage, we again employed a tampon of cotton, which was kept in place by a T-bandage. A pledget of cotton was covered with the ointment and placed against the os before the tampon was introduced. The tampon was allowed to remain for an hour, when it was removed. The os had not changed, and was as rigid as before. The head had not descended very much, though its position was normal and the pains fairly strong.

Stimulants were administered, and, to promote better circulation in the cold limbs, bottles of hot water were placed at the feet and along the legs.

At about seven o'clock, Dr. W. A. Chandler arrived. By his advice, milk was administered in addition to the whiskey, and hot-water injections directed against the os. These injections were kept up for some time, but without evident effect. The belladonna ointment was again resorted to, and efforts at dilatation made with the fingers. When the fingers of one became tired, another took his place, and so the three physicians alternated in their efforts to bring about dilatation. A suppository, which had been ordered prior to the arrival of Dr. Chandler, containing one grain each of the extract of opium and belladonna, was inserted into the rectum. Efforts to make the uterine contractions stronger and more effective were made by pressure over the uterus, and attempts made to bring the head lower down. At eight o'clock the os had so relaxed as to permit the skilful introduction by Dr. Nash of a small pair of Simpson forceps; but, immediately following their introduction and locking, the os again firmly contracted and further complicated matters by forming a tough and seemingly unyielding ring around the shanks of the forceps, through which it was at first impossible to bring the head. It was therefore with much difficulty that the head was brought down to the perineum, which was not accomplished for three-quarters of an hour. At this point the instruments were removed and nature made to effect the rest of the delivery, which it did in about ten minutes, without a tear of either the cervix or perineum.

The child was dead, as was expected from the fact that fœtal movements had ceased more than three hours before. It was not injured in any way, nor did it show any marks of the forceps. It was of the average size of a seven and a half months' fœtus. The bones of the head were softer and the fontanels larger than usual, but in all other respects it was normal and healthy. After the birth of the child a little time was allowed to elapse before the expression of the placenta, for there was no more than ordinary bleeding. The placenta was finally removed without difficulty, perfect uterine contraction secured, and a binder and compress applied.

An examination of the placenta showed that one-third only of its surface was normal in appearance; the other two-thirds was dark with clotted blood, and in marked contrast

with the normal condition of placental tissue. This changed portion of the placenta had evidently been separated from its uterine attachment, and was conclusively the cause of the hemorrhage. This hemorrhage was twofold, coming, as it must have done, from both the uterine and placental surfaces, and because of the latter character the death of the child in utero is very readily accounted for.

For some little while after the removal of the placenta our patient rested very easily. She was perfectly rational, complaining only of a little smarting at the genital fissure, and was disposed to assist herself if she had been permitted. The uterus had firmly contracted, and the amount of bleeding continued to be normal. Her pulse was rapid, her features blanched, and her extremities cold; but there was cause for believing that, under the stimulating influence of whiskey and milk and the observance of quiet, she would rally very well. We were, of course, afraid of shock, but at this time we had little reason for expecting it to be very great. However, this favorable condition of things did not last very long, for symptoms set in which excited alarm. The pulse became so rapid and feeble as at times to defy counting, the speech became wild and delirious, and the patient restless and determined to get out of bed. She became oblivious to the fact that her child had been born, and complained that we were pulling too hard upon the forceps. The extremities became colder, the hands lost their warmth, the lips became deathly, and the eyes gradually assumed a staring look. Her strength slowly gave way, and at about half-past nine it was evident that death was creeping upon her. Consciousness ceased, and the respirations became stridulous. Tincture of digitalis and carbonate of ammonium were ordered, the administration of stimulants continued, and every possible effort made to arouse her; but all was in vain. At a little after ten o'clock she died.

REMARKS.—The above case is interesting only because of the complications. The mortality of accidental hemorrhage, *per se*, unless concealed, is not very great, but the complication with a rigid os affects very seriously the prognosis. If the case had been one simply of hemorrhage, the treatment would have resolved itself into the dilatation of a normal os, the administration of ergot to its physiological limit, the firm contraction of the uterus by abdominal pressure, and the consequent speedy delivery of the child. Ordinarily this is very quickly done; but in the case under consideration six and a half hours' tedious effort was requisite to bring about such a result, and then, unfortunately, too late to save either mother or child.

A rigid os is at all times troublesome, but the worst thing to fear in such cases is at the most a protraction of the labor. So that either of these two conditions occurring alone need not necessarily occasion alarm; but united they offer cause for grave apprehension.

The use of ergot in cases of accidental hemorrhage is commendable, but its undoubted action upon the circular fibres of the cervix contra-indicates its use when there is rigidity of the os. Prior to my visit to the patient one drachm of the fluid extract of ergot had been administered, but until the head was brought down upon the perineum no more than this one dose was given.

If we could have had a Barnes' bag, dilatation *might* have been brought about a little earlier, but, owing to the circumstance that the day was Sunday and we were far removed from anybody who had one in his possession, none could be procured. However, the use of the fingers very rarely fails to secure dilatation, and it is doubtful if a Barnes' bag would have given us any very efficient aid. The os was so contracted the greater portion of the time that it was a question whether a Barnes' bag could be introduced.

Chloroform and chloral could not be used, on account of the condition of the patient, and nipping the cervix with the scissors to allow the immediate application of the forceps did not meet with the approval of all the physicians.

One other complication which contributed to the prolongation of the labor was the position of the os. At each examination it was necessary to carry the finger far up to the right and pull the os forward to the median line, and keep it in this position as long as possible. This condition was evidently due to a malposition of the uterus at the time of pregnancy, development then not taking place symmetrically.

The cause of the placental separation could not definitely be ascertained. We had no knowledge of any accident that might have caused it. It has been mentioned that on the 8th of the month our patient had a severe attack of pain with diarrhœa, and that during the latter months of her pregnancy she had œdema of the lower extremities; with this œdema there may have been albuminuria. Our patient was anæmic during the last week,

but her pale appearance was attributed to the results of the diarrhœic attack. It is impossible to do more than conjecture as to whether any one of these conditions gave rise to the placental separation. The patient was exceedingly anxious to have her child, and, when questioned, denied having made any attempt at abortion.

The death of the child was evidently due to hemorrhage.

The death of the mother was unexpected. Whilst the loss of blood prior to the visit of Dr. Nash was great, and would soon have ended the life of the mother if not controlled, the loss of blood from the time of his visit to her death was not more than many women suffer in childbirth without showing the least symptom of depression. Her strength during the entire ordeal was remarkable, and after the birth of the child was for several minutes of such a character as to be cause for congratulation. The weak pulse, however, and the cold extremities were sufficient warning for us to anticipate a reaction. But symptoms of shock quickly supervened, and all efforts to arouse the patient were futile.

2048 North Eleventh Street.

THE RELATION OF THE MEDICAL COLLEGES TO PRELIMINARY EDUCATION.

BY PETER D. KEYSER, A.M., M.D.,

Fellow of the American Academy of Medicine; Professor of Ophthalmology, Medico-Chirurgical College, Philadelphia, Pa.

(*An abstract of a paper read before, and published with the imprimatur of, the American Academy of Medicine, at its Annual Meeting, held in Baltimore, Maryland, October* 28 *and* 29, 1884.)

THE principal objects of this Academy are to encourage preliminary education of a high standard before entering upon the study of medicine, as well as to elevate the profession,—that is, to raise the educational qualifications of the profession. In attempting to carry out these objects, it is the intention to persuade, if possible, the medical institutions of instruction to assist us in this laudable movement by raising their requirements for matriculation, instead of that of the payment of a fee only; and also to elevate the educational qualifications of the profession by enlarging the curriculum and lengthening the time of study to three and four years in graded courses, so that a more extended and thorough knowledge of medicine can be obtained before granting the degree and placing the graduates before the public as medical practitioners.

Two years after the organization of this Association, the Pennsylvania State Medical Society took up the subject at its meeting in May, 1878, and passed a law forbidding any of its members accepting students lacking the prescribed educational qualifications, to determine which every county medical society has been obliged to appoint annually a committee to examine every one desiring to study medicine, before being accepted by a preceptor.

The State Board of Health of Illinois, under the personal exertion and supervision of its able secretary, Dr. John H. Rauch, has made herculean efforts and accomplished very much in requiring the proper and efficient education of the physicians practising in that State. It has given the key-note to all the other States having a State Board of Health. From the action taken in Illinois, many of the schools throughout the country have changed the curriculum to a higher standard for both matriculation and graduation,—that is, have advertised such changes; but we will see later if they are honestly meant and will be carried out.

The great trouble and opposition come, unfortunately, from the older and leading schools, especially those in the larger cities, where quantity rather than quality is looked at, and thus the country is flooded with physicians, many of whom have the degree, with little if any qualifications to support it.

In looking over the Fifth Annual Report of the State Board of Health of Illinois, some very interesting facts in relation to the position taken by the various medical schools in the United States on the necessity of a preliminary education before admission to the study of medicine are to be learned.

According to the Report, the total number of medical schools in the country is ninety-one. The number now exacting an educational requirement as a condition of matriculation is sixty-one, where heretofore only thirty classed themselves in favor of an elevated standard.

The total number requiring attendance on three or more courses of lectures before graduation is sixteen, while forty-three

recommend, but do not compel, such attendance.

Fifty-six regular colleges and universities publish that certain preliminary requirements are necessary for matriculation. But in this list of schools there are some, perhaps many, which really should not be classed with those in favor of higher education for the student and practitioner of medicine. Some of these institutions have set their requirements at so low a pitch that it would have been fairer and more honorable to have said, "Requirements, none. We want students and money, and not a higher standard of education."

Let us see, from their own reports, what their requirements are:

"Evidences of at least a fair English education."

"Evidence of a good English education."

"If necessary, an examination by the dean or registrar."

"Evidence of a good English education."

"Preliminary education and training sufficient to enable him to profitably and properly engage in the study of medicine."

"A creditable English education."

"Sufficiently advanced in an English education to study medicine."

"Evidences of a fair preliminary education."

"A good English education."

"A good common-school education."

"At least a thorough English education."

"A certificate from a student's preceptor of his moral character, and that he is duly entered and properly qualified to study medicine. The responsibility of sufficient preliminary education rests, of necessity, with the private instructor."

"The responsibility of preliminary qualification must rest with the private instructor."

"Evidences of a good ordinary English education."

"An examination, if considered necessary."

All these requirements are very weak, and their enforcement improbable. In the schools where evidences of a good, fair, or thorough English or common-school education are mentioned as necessary for matriculation, nothing is said as to how these evidences are to be obtained; and "An examination, if considered necessary," is so far from the mark that nothing said would have been better. Still worse is the putting the responsibility of preliminary qualification on the private instructor. It is shoving the responsibility with a vengeance. And these schools are accepted by the State Board of Health of Illinois!

Now, can or should these institutions be classed with those who are brave enough to say to the world, "We purpose assisting in the higher preliminary education in the medical student in this country in perfect honesty and good faith"? I claim not; and therefore, making the deduction, there are but forty-one regular colleges in this country which are properly professing to raise the standard of education. Again, how many of these forty-one carry out to the letter that which they profess to do? I am sorry to say but few,—from what I learn directly, so few that it astonishes me that the State Board of Health of Illinois is so deceived by the mere declaration or announcement of many of these schools that they can accept their diplomas without a State examination. If all the schools should declare in their announcements, as a mere cover, that evidences of a good English education are required for matriculation, and continue the free and loose way of matriculating any one paying the fees, and still persist in pursuing the old course of delivering twice in two years the same lectures, the State Board of Health of Illinois and of the other States having the same rules and customs will be greatly deceived, and still permit some as poorly prepared and improperly educated physicians in their State as in former years. Only a short time ago I heard a high officer and professor of a medical school say, "We wish to do all this in relation to the preliminary qualifications; but what are we to do with the students who come to us? We must admit them." Let me say there is no "must" about it, if there is honesty in the intention of elevating the standard of the profession, and the schools will look at it in that light instead of from a monetary point of view.

At two of the meetings of the Pennsylvania State Medical Society since 1880, I heard reports from some of the county societies, in which it was stated that young men rejected by their committees on preliminary examination, and recommended to take a course of study in a good Eng-

lish and classical seminary previous to their entering upon the study of medicine, had been matriculated almost immediately after in medical schools which claim to require preliminary educational qualifications before matriculation.

I have been informed by many graduates, as well as by students, that when they matriculated no questions in relation to their educational qualifications were asked. The presentation of a letter from some physician, especially a former graduate of the school, acting as preceptor or friend, with the conventional fee, was all that was needed.

All this is not sustaining the effort of the State Medical Society to elevate the profession. Certainly higher education in the medical profession is as necessary as in the other learned professions, if not even more so, for the correct understanding and judgment of the complicated studies relating to it. A high conservative power is wielded by it for the well-being of the whole people, and every legitimate means should be used to foster and enforce it, especially by government laws; and the sooner every State has a Board of Health, with a committee of examiners of highly and thoroughly educated physicians to examine and license every one desiring to practise medicine, no matter from what institution the diploma is obtained, the better it will be for scientific knowledge, the standing of the profession, and the interests of the people.

There are thirty-six schools which have no preliminary requirements for matriculation, and which take all who come, educated or not, who are able to pay the five dollars matriculation and fees.

Of the number of matriculants of the different colleges, those advertising preliminary requirements of some kind had last year 4393, while the no-requirement institutions had 5808, as far as can be obtained. This shows the readiness with which constant overcrowding of the profession takes place, the colleges graduating many who, from the want of proper mental training, are entirely unfit to contend with others who have been so favored by the proper and necessary education to grasp the thoughts and requirements of the thorough study of medicine, as to be able to show to the world that they represent a learned and liberal profession, and claim to rank as peers among educated men.

TRANSLATIONS.

The Use of Caffeine in Cholera.—At the November meeting of the Société de Thérapeutique, Paris, M. Dujardin-Beaumetz endorsed the recommendation of M. Huchard, of hypodermic injections of caffeine (.10 gramme, or 1½ grains) repeated several times daily, but insisted upon its administration in combination with benzoate of sodium, a substance in which it readily dissolves. Among the many remedies vaunted for cholera, some are good, a few are inoffensive, but there are some which are positively bad, and among these he would class subcutaneous injections of morphine, which are so generally recommended.

Taking a broad view of the disease from the stand-point of therapeutics, there are two varieties of cholera patients,—those who micturate and those who do not. When the morphine is given by subcutaneous injection, in the latter class, three things may happen: it is not absorbed, and remains where it is deposited; it is absorbed without being eliminated, and poisons the patient; or, finally, where taken up and eliminated consecutively, it may exist in too great a quantity in the system. It is, therefore, a dangerous remedy; but we should not on this account entirely banish opiates from the treatment of cholera.

M. Dujardin-Beaumetz equally and alternately employs subcutaneous injections of caffeine and of ether. He also proposes to try the treatment now employed by M. Hayem at the Hôpital St.-Antoine,—viz., when it is found that, in spite of stimulants of all kinds, the cold stage has been reached, there are injected into the veins two and one-half litres (five pints) of a solution of sodium chloride and of sodium sulphate at a temperature of 38° Cent. The patient, it is said, at once revives, when, profiting by his intense thirst, he is made to drink large quantities of alkaline solutions. This is done because the blood is always acid in cholera subjects. This method appears to have already given good results. One thing is certain, however, that it is entirely inefficacious among alcoholic subjects.—*Le Progrès Médical.*

Opening of Mastoid Process.—Dr. Schwartze, of Halle, at the International Medical Congress, discussed the operation

of opening the mastoid cells, and gave the following as indications for operative interference:

1. In acute inflammation of the mastoid apophysis with retention of pus in the bony cells, if, after the application of antiphlogistics and Wilde's incision, the œdematous swelling, the pain, and the fever have not subsided.

2. In chronic inflammation of the apophysis, with subcutaneous or subperiosteal abscess, or mastoid fistula, and in this case even when symptoms do not exist of a nature to compromise life.

3. When, the mastoid being normal externally, there exists a cholesteatoma or a purulent collection in the middle ear which cannot be removed by ordinary methods, and when serious symptoms arise, or if an abscess from congestion is formed in the posterior wall of the auditory canal.

4. The external surface being healthy, and in the absence of purulent collection in the middle ear, if the apophysis is the site or point of departure of headaches intolerable and persisting for a long time, against which other remedies have been employed without effect.

The operation is of doubtful expediency in chronic incurable otitis media, where signs of mastoid inflammation are wanting and there is no retention of pus in the middle ear. The operation is contraindicated when there is certainty of metastatic abscesses being already formed, or in the presence of a secondary meningitis, or of an abscess of the brain.

Conclusions.—1. The operative opening of the mastoid apophysis is a valuable remedy against some of the gravest and most dangerous diseases of the ear. 2. The danger of the operation should be considered as light in comparison with that of the disease which it is intended to relieve.—*Annales des Maladies de l' Oreille*, etc.

On Compressibility of the Brain.—Professor Adamkiewicz presented a communication to the Society of Physicians of Vienna, on compression of the brain. He briefly recapitulated the results of his former experiments concerning pressure of the brain, given in a previous lecture, then passed on to the relation of the compressibility of the nerve-masses. It is easy to prove the compressibility of the brain-matter. If one fits a piece of laminaria in the brain of a rabbit, after a few days it is swollen, and the brain-substance locally depressed. The brain, however, has remained quite normal in all its layers, and is consequently compressible. This fact is, therefore, proven. The leading authorities upon the subject teach that a tumor which generates itself in the brain causes increased tension of the cerebro-spinal fluid, and, as a further consequence, compression of the vessels and anæmia. In order to answer the questions, how do the blood-vessels act during intra-cranial tumors? and does the resulting anæmia occur through compression of vessels? he again inserted laminaria tents. This time he bled the rabbit to death, and then injected the blood-vessels. It was demonstrated that they were hyperæmic at the point of compression; also that a fluxion had afterwards occurred, on account of the paralysis of the muscles caused by the pressure. The compression of the brain-tissue therefore does not ensue at the expense of the vessels, nor at the expense of the incompressible liquor. It must be due to a condensation of the cerebral tissue itself. x.

Hydrocele in Woman.—Prof. Hennig, of Leipsic, read a communication upon this subject in the *Versammlung Deutsches Naturforscher und Aerzte*, in which he systematically considers the anatomy, etiology, clinical varieties, diagnosis, and treatment of this rare affection. He had found in medical literature forty-one cases, two of which had been under his care. Often the effusion in the canal of Nuck is complicated by protrusion of some of the viscera, which possibility must be taken into consideration. In some cases simple puncture, in others injection of iodine, was sufficient to obtain complete occlusion of the sac. Excision of part of the sac and packing the cavity with charpie, and in one case the ligatures (of iron wire), were also successful.—*Deutsche Medizinal Zeitung*, October 16.

Coffee made with distilled water is said to possess delicacy of taste, improved aroma, and, in short, is more agreeable and acceptable in every way, possibly because the distilled water does not take up any of the tannin from the berries, which ordinarily is rendered soluble by the earthy carbonates.

EDITORIAL.

DIABETES MELLITUS FROM A PHYSIOLOGICAL STAND-POINT.

DALTON'S investigations concerning the bile demonstrated the fact that this fluid is discharged into the intestine principally during digestion, while food is passing through the duodenum. It is highly probable that a similar provision for intermittent activity exists with regard to the discharge of liver-sugar into the blood passing through the hepatic vein. As this sugar, when assimilated, is directly concerned in supplying energy to carry on various activities of the body, and as these activities are not uniform and constant in their operation, it follows that there must be some nutritive mechanism which regulates the glycogenic function of the liver so as to regulate supply in accordance with demand; for it is well known that the amount of sugar in the general circulation is almost constant, the normal proportion of sugar in the blood being put down by Frerichs at 0.12 to 0.33 per cent. Recalling the statement of Von Becker, that when in rabbits the proportion of glucose in the blood exceeds 0.50 the urine will contain sugar, the question is pertinent, and has been frequently asked, What are the conditions giving rise to an excess of sugar in the blood? The answer to this will indicate in what direction we are to seek for the pathology of diabetes mellitus.

The statement is commonly made—probably in imitation of the separation of jaundice into the two classical forms of reabsorption and suppression—that diabetes may be due either to increased production of sugar by the liver, or to its defective assimilation by the various organs of the body. With regard to the latter supposition, on looking at the subject from a physiological stand-point we cannot see the slightest warrant for the supposition that glucose ever accumulates in the blood owing to defective assimilation by the tissues. On the contrary, there is a strong probability that the supply of sugar taken up by the blood is efficiently regulated in health, in accordance with the demands of the body, by a nervous mechanism acting through the vaso-motor and trophic nerves of the liver itself.

When the blood contains an excess of glucose the conclusion is at hand that the hepatic nerve-supply is in some manner disturbed, thus permitting the blood-serum to convert a greater quantity of glycogen into glucose than can be utilized in the immediate demands of the economy, and to wash the excess through the hepatic veins into the general circulation, where it acts finally as a diuretic in its escape through the kidneys. In point of fact, this hypothesis of the production of true diabetes is supported by Bernard's classical experiment of puncturing the floor of the fourth ventricle, and by various forms of nerve-injury, all of which, according to Cyon and Aladoff, are effective in causing diabetes only through paralysis of vaso-motor nerves, thus permitting a more rapid flow of blood through the glandular tissue of the liver. Moreover, it has been repeatedly demonstrated that the serum of the blood, at a moderately-warm temperature, has the power of converting glycogen into sugar. It is only necessary, therefore, to cause an increased quantity of blood to flow through the liver in order to increase the proportion of glucose in the general circulation.

An efficient cause of diabetes must therefore exist, in general, in all those agencies capable of disturbing the normal action of the vaso-motor nerves, the gravity of the disease depending directly upon the

degree and persistence of this disturbance. Diabetes appears, therefore, in certain cases of cerebral hemorrhage or meningitis consecutive to injuries to the cranium and accompanying neoplasms of the medulla. It may also appear from psychic excitation, as persistent emotion (Frerichs) or mental strain; and in certain nerve-disorders, as neuralgia, or nerve-injury. It is possible in some cases of diabetes that there may be a wide-spread degeneration of nerve-structures accompanying the rapid waste of the body and general disorder of nutrition rather than a definite local lesion. The glycosuria following chloroform-inhalation, muscular exercise, and surgical operations upon the abdomen is transitory, because the reflex vaso-motor disturbance rapidly subsides. The influence of poisoned blood in producing temporary glycosuria may be explained in a similar manner.

There is a class of cases of intermittent glycosuria in the production of which the liver may take no part whatever. Here physiology must again be called upon to elucidate clinical phenomena. Under ordinary circumstances, the lacteals principally carry into the thoracic duct emulsified fat, the capillary blood-vessels appropriating the glucose and albuminose formed in the process of digestion and absorption. A very slight alteration of conditions, and the chyle may take up an excess of glucose and deliver it into the subclavian vein without the liver ever having an opportunity of converting it into glycogen. As the total quantity of chyle, according to Bidder and Schmidt, is thirty pounds daily (or about twice the total volume of blood in the vessels), it is evident that a slight excess in the chyle would cause a very decided increase in the proportion of glucose in the blood directly after a meal. This would be more likely to occur after the ingestion of honey or maple-sugar, or of sweet fruits. The occurrence of sugar in the urine of rabbits fed upon carrots after several days' fasting might be explained in this manner.

Glycosuria may also be due to some abnormality, some unknown chemical or physical change in the liver-sugar which makes it less easy of assimilation by the tissues and more irritating to the kidneys. The glucose that occurs in the urine may not be vitally identical with normal liver-sugar and yet be chemically indistinguishable from it. Starch and glycogen are alike in chemical composition, but differ in their properties. In point of fact, this difference between liver-sugar and other varieties of sugar (including glucose artificially made from starch) was long ago recognized by Bernard.*

Several classes of glycosuric diabetes may now be recognized: first, the form in which there is a nerve-lesion more or less extensive, and whose effects upon the glycogenic function of the liver may be permanent; in this we recognize the fatal form of diabetes, which, in the absence of a better designation, might be called the *neurotic* form, or diabetes mellitus; secondly, a form in which there is a transitory nerve-disorder, whether of reflex origin or caused directly by vitiated blood, which might be termed *functional* glycosuria; and, thirdly, a form connected with chylification, which might be termed *digestive* glycosuria. Possibly, to these may be added a rare form with obscure etiology (probably, as above suggested, connected with abnormality of secretion), which might be designated *essential* glycosuria. There may be other varieties of diabetes (for instance, that accompanying pancreatic disease), but these at least illustrate the fact that glycosuria as a symptom is susceptible of several explanations, although the differential diagnosis may in some cases be practically impossible at present.

THE LABORS OF THE LUNACY BOARD.

WE have already had occasion to notice the success of the Lunacy Committee of the State Board of Public Charities in detecting cases of improper detention and inhuman treatment of isolated cases of insanity in different parts of the State. Although the law of 1869 placed it within the power of any individual to compel the removal of insane persons manifestly suffering from want of proper care or treatment, yet this law was seldom invoked, because it was the business of no one in particular to search for such cases, and the neighbors, especially in country districts, shrank from the consequences of reporting such cases when they were known to exist. It was only in August last that the Committee went actively to work and sent out circulars of inquiry to the physicians of Pennsylvania. As a result, they have been able to report to the State Board eighteen cases of alleged improper treatment which they had investigated, in some of which gross neglect and wanton cruelty had been practised. Several of these have been already removed to State hospitals, and new cases are constantly coming to light. Dr. Morton and the Secretary, Dr. Ourt, recently investigated four cases which had been kept chained in out-houses, like beasts, for periods of from five to sixty-five years, and took steps to secure proper care for them. In view of these aggravated instances of neglect which it has discovered, the Committee recommend the passage of a law making it a misdemeanor for any one to improperly detain or conceal an insane person of mature years.

A gratifying feature in the work of the Committee is the cordial manner in which the members have been aided in the discharge of their duty by the profession throughout the State, and the readiness with which their recommendations, as a rule, have been adopted by those having the insane in charge, which has rendered their labors much less arduous than they had anticipated.

A FATAL ENDEMIC BOWEL-DISORDER IN VIRGINIA AND KENTUCKY.

IN Southwestern Virginia and Eastern Kentucky a peculiar endemic has lately been raging, in which whole families have perished, the total mortality being variously estimated at from three hundred to a thousand. The district afflicted is about seventy by eighty miles in extent, situated on the slopes of the Cumberland Mountains in Eastern Kentucky and principally in Lee and Wise Counties in Southwest Virginia. The outbreak is attributed to a prolonged drought, which has made the water-supply low, the streams being more than usually charged with mineral and vegetable substances.

In the newspaper accounts the disease is described as having some appearances of cholera, being characterized by great thirst, cramps, frequent and profuse watery discharges from the bowels, and rapidly-fatal course, death occurring in from two hours to as many days. In Wise County, Virginia, where the epidemic is still in existence, it is said that deaths have been so numerous as to make it difficult to provide for the proper burial of the victims.

We await the medical accounts of this epidemic with interest, and hope to publish a further account of it. Possibly it may throw some light upon the pathology of the "black tongue" disease, a strange epidemic which ravaged many parts of this country from 1841 to 1846, and which was called epidemic erysipelas for the want of knowledge as to its real nature, although Bennett found that not more than one-sixth of the cases showed the customary external evidences of erysipelas.

NOTES FROM SPECIAL CORRESPONDENTS.

CINCINNATI.

IT was supposed that the inundation of a large part of our city last February would result in an increase of sickness. This has not been the case. On the contrary, the health of the city has never been better than during the summer and up to the first of the present month. This condition may be partly due to the general cleaning up which followed the flood throughout the entire submerged district.

Within the last month, however, there has been an increase in sickness, and two weeks ago the death-rate from natural causes was higher than it has been since the smallpox epidemic of 1882.

Diphtheria and scarlatina prevail in almost an epidemic form in some quarters of the city. The central part of Walnut Hills is especially affected, where the drainage is bad and efficient sewers have not yet been constructed. A number of the students of Lane Seminary, situated in central Walnut Hills, have been affected with what in some cases was pronounced diphtheria and in others tonsillitis, the diseases seeming to be not easily differentiated. The fact that scarlet fever and diphtheria are raging in the same quarters at the same time may lead to some interesting facts as to their relation.

The medical colleges are all complaining of a comparative dearth of students. This is possibly due to the financial distress under which the whole Western country is laboring. Many one- and two-term undergraduates are practising medicine in remote country districts in order to earn money to take them through college.

The Ohio Medical College, being the largest, suffers the most, the shortage, compared with the last half-dozen years, being perhaps twenty per cent. In this college there have been no changes in the regular faculty. Among the new assistants, Dr. David Debeck, Professor Seely's assistant in the Eye and Ear Clinic, has been doing some very good work. Fresh from a course in the German universities, he is rendering valuable service to the clinic, and has infused new life into the private courses of that department. Dr. Roeder, the late demonstrator of chemistry, having during the summer died of apoplexy, Dr. W. S. Christopher has been appointed to fill his place, which he does with marked ability.

The Miami College has almost the usual number of students, although the number of late arrivals is not so great as usual. Dr. Clendennin has been made dean of the faculty instead of Dr. John Murphy, and also fills the chair of surgery left vacant by the removal of Dr. Kearny to Knoxville, Tennessee. The city, no less than the college, feels the loss of Dr. Kearny, who is not only a skilful surgeon, but also a perfect gentleman. The chair of anatomy vacated by Dr. Clendennin has been well filled by the appointment of Dr. F. W. Langdon, of some considerable celebrity as a field naturalist and comparative anatomist, as well as a rising physician. The faculty is certainly strengthened by this addition. Dr. Langdon's place of demonstrator of anatomy has been filled by Dr. Eric E. Sattler. Dr. W. A. Rothacker, Pathologist to the Cincinnati Hospital, has been made Lecturer on Pathology, since which time this ordinarily dry subject has become the most interesting one in the whole course.

The Board of Health is now wholly in the hands of non-professionals, and its work is not nearly so satisfactory as when the health officer was a physician. The sanitary condition of Cincinnati, taken as a whole, was, perhaps, never worse, and there seems to be no prospect of a change before the next spring.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a meeting of the Society held October 8, 1884, Dr. William M. Welch, President, in the chair, Dr. J. V. Crandall read a paper upon "Croup," in which he urged a more careful diagnosis between this condition and diphtheria, and advocated tracheotomy, and reported eight cases in which it had been performed, with five recoveries.

DISCUSSION ON CROUP.

Dr. J. Solis Cohen, in opening the discussion, said: The principal impression gained from this paper is the importance of tracheotomy. As regards the identity of these diseases, while I contend that there is a difference, I am not prepared to recognize so great a difference as is claimed by the reader of the paper. Croup and diphtheria do not present in the alleged proportionate frequency. True membranous croup is a very rare disease, and that is the reason so many disbelieve its existence. The series of successful tracheotomies reported by Dr. Crandall is very remarkable, and I trust that in future his success may continue to be as great. It is certainly greater than any that has been reported in this or any other city probably in the United States. Some years ago (1873) I prepared a paper for this Society, in which the results of more than five thousand cases were given. The proportion of successful operations was about one in

four. Before that paper was presented, operations had been rare in Philadelphia; since then they have become more frequent. The ratio of success is not always maintained in one's later experience. Thus, the late Dr. Hodge, who at one time reported four cases, three of which recovered, told me that he had subsequently operated seven times in succession without another recovery. Dr. Jacobi, whose success had been exceptionally good at one time, informed me some years afterwards that he had been so unfortunate as to lose one hundred cases in succession, and thus his early confidence in tracheotomy has been modified.

The reason for this variation of results is, I think, plain. We are careful of our first cases. We see them frequently after operation, just as the writer of the paper has done. When we become older, this time is not at our disposal. The after-nursing I regard as of the very highest importance, and I have long made it a rule never to operate unless sure that this will be properly attended to. The time for operation is a question of great moment. The best rule is to operate as soon as the thought of the necessity comes into your mind. Success depends on early operation, other things being equal. The tube appears to me to be a necessity. To dispense with it I regard as dangerous, notwithstanding it is thought by some to produce irritation and thus favor the deposit of new membrane. A few years ago, impressed with the encomiums of Dr. Martin, of Boston, I adopted the plan of keeping the edges apart by ligature without a tube; but inattention in nursing allowed the opening to become so frequently occluded by the soft parts, in the motions of the child, and suffocation, fortunately overcome at the moment, having ensued on one occasion, I have felt no desire to repeat the experiment.

Steam in the room and the maintenance of an equability of temperature are important. If I had but two things to depend upon in croup, I would choose vapors from slaking lime. But a small piece in a pan of water upon the stove will not answer. Copious disengagement of vapors is needed, just such as were produced by the ignorant Irishman mentioned in the paper. I have no notion that the action of the lime is chemical, although I am aware of its slow action on membrane in a test-tube. I believe that it acts mechanically. Small particles of lime are carried up with the vapor of water; these get under the false membrane, which does not everywhere hug the tissues closely, and act as minute wedges; the accompanying vapor of water follows and detaches the products.

I believe that I have seen life saved more frequently by lime used in this manner than by tracheotomy. Dr. Crandall has been fortunate in braving the contingencies that surrounded some of his cases. There are very few men brave enough to operate without adequate assistance, and with the light furnished by an uncertain lamp. Anomalous blood-vessels often give unexpected trouble.

As regards the point of incision, my own plan has been to perform the low operation; that is, the one below the isthmus of the thyroid gland. A larger tube can be inserted there, and the wound is farther from the seat of disease. It is true this is the more difficult operation, but there is no occasion for a hurry, unless immediate death is threatening. The ten or fifteen additional minutes required for a deliberate operation steal nothing from the patient's chance of life. In an emergency of course there is no choice. All the tissues may have to be incised in one cut. Another fact rendering the lower operation more favorable is the lessened liability of coming directly upon masses of pseudo-membrane which may be forced down the trachea in the very act of incising it.

An important point, too, not appreciated by the majority of operators, is that this false membrane is a foreign body, and should be removed. The first thing to be done after the trachea is opened is not to put in the tube, but to make a thorough search for false membrane, and to remove all within reach. Then the edges of the cut should be kept asunder and cough be excited to drive more out. If this were done more frequently, the statistics of recovery from the operation would be much more favorable.

We sometimes have hemorrhage to deal with. The best method to treat this is to plug the wound about the tube with absorbent cotton. Never hunt for the vessels; pressure gives the best results. The character of the tube is important; these are often found made of hard rubber, but I do not consider such material desirable. It is thicker than silver, thereby lessening the calibre, and does not tarnish when the wound goes wrong; and this latter characteristic of silver tubes is frequently of service. The tube should be of equal calibre throughout, and not made tapering, so that the patient may get all the air he is supposed to get.

In answer to an inquiry from Dr. H. R. Wharton as to his use of chloroform, Dr. Cohen replied that the operation was made easier by anæsthetics, but the safest plan is not to use them. Ether is out of the question if ordinary artificial light be close. The patients were usually numb and insensitive from impending carbonic acid poisoning, and when retaining sensibility often seem to understand the purpose of the operation, and do not struggle. Struggling should be prevented by wrapping the trunk and limbs in a sheet or a towel.

Dr. H. R. Wharton: I agree with Dr. Cohen, that the results of Dr. Crandall's

operations have been remarkably successful. The results of my own cases have been fairly encouraging.

As to the two diseases under consideration, I believe in their non-identity. With Dr. Cohen, I am opposed to the use of an anæsthetic in the operation of tracheotomy, and believe that I have seen two cases lost through its use. The after-treatment of cases of tracheotomy, when performed for croup or diphtheritic croup, is most important, and I consider a moist atmosphere very necessary in these cases. At the Children's Hospital, in this city, we have a room especially fitted up for tracheotomy cases, which can be readily filled with the vapor of steam from steam-heating pipes. The permanent removal of the tracheotomy-tube has, in my experience, often been a matter of greater difficulty than its original introduction. I recently had a case in which the tube was removed on the thirteenth day; the condition of the patient was good, the temperature and pulse being normal. An attack of dyspnœa supervened two hours after the removal of the tube; the gentleman left in attendance was unable to reintroduce it, and when I arrived the child was dead. I have performed tracheotomy five times for diphtheritic croup, with two recoveries; one of the fatal cases was the one just alluded to, which died on the thirteenth day after the operation, from an accidental cause.

Dr. J. M. Barton: I regret that Dr. Cohen has not given a more definite rule "when to operate" than "when you begin to think of tracheotomy, then is the time to do it." As soon as you make a diagnosis, and perhaps before you make a diagnosis, of membranous croup, you think of tracheotomy. I was called in two cases lately by recent graduates to perform tracheotomy in croup. Doctors, parents, and friends were all urgent for immediate operation; they were evidently under the impression that it meant without operation certain death, with operation instant recovery; the cases were not urgent, they both had croup, but there was no important obstruction to respiration; under careful treatment, which had been neglected, they both recovered without tracheotomy. My own rule has been, when the tissues just above and just below the sternum decidedly recede during inspiration, when the face becomes slightly livid and the respiration hurried, with the usual symptoms of croup, the time to operate has arrived.

I have not found ligatures of much use in keeping the wound in the trachea open. In operating low down in a young child, with small and deep trachea, the ligatures pull directly towards the surface. A probe bent into a circle and a hook fashioned on each extremity will keep the wound open by its spring, until a properly fitting tube can be obtained.

Is it desirable to operate *in extremis?* I have operated on several such cases in which artificial respiration had restored them, but they all perished in from one to three days.

Dr. Nancrede: I have been much interested in the excellent paper read by Dr. Crandall, but dissent from the evident impression intended to be conveyed by the writer, that tracheotomy is a trivial operation and one which may be undertaken without any hesitation. I am not ashamed to rank myself with those surgeons who dislike such operations, especially when so bold a one as Billroth says that he blames no surgeon for declining to perform laryngotomy on a young child. This may seem exaggerated language, but although in the majority of cases the operation is a simple one, yet it may demand all the surgical skill and nerve that the surgeon is possessed of, as in the last tracheotomy I performed. Two cases have been related this evening in which death occurred during the operation by most competent operators. Billroth has had a similar experience, and I know of a number of others.

An otherwise good, general practitioner, with a previous hospital experience, sent for me on one occasion, saying that he had opened the trachea, but could not introduce a tube. Upon examination, I discovered that he had sliced off a portion of the right ala of the thyroid cartilage, but had failed to open the trachea at all. Other operators had cut either the normally or abnormally placed carotid artery, or had dissected between the trachea and the carotid artery until they had reached the vertebræ. Other accidents have also happened, which should make us pause, while we recall the fact to mind that if we do not get through the operation successfully we kill our patient. I cannot resist the impression which my experience has produced, that diphtheria and pseudo-membranous croup are identical diseases, modified by their locality, rapidity of progress, etc. Diphtheria is said to be distinguishable from croup by the presence of albuminuria, but German investigators have shown that albuminuria exists in a distinct proportion of cases of so-called croup. Besides, most croup cases *die* before this symptom can make its appearance. Moreover, all cases of undoubted diphtheria do not present at first, or at any time, those profound alterations of the blood and the kidney-lesions which result in albuminuria.

Finally, whether the diseases are identical or not, clinically it is generally impossible to distinguish them at the time of operation. I may refer to a series of cases in my own practice, which would have been decided by any member present as typical cases of true croup, which yet, by their subsequent course—even diphtheritic paralysis—or their marked contagiousness, proved to be undoubtedly diphtheria. The difference in character of

the false membrane in the pharynx, larynx, and trachea seems to be relied upon by some of the speakers as a proof of the essential difference of the two diseases. Precisely similar conditions are found in undoubted diphtheria, and are explainable on anatomical grounds, so that the membrane of croup and the membrane found in the trachea in undoubted diphtheria are identical in appearance, etc., being in the substance of the mucous membrane *in the pharynx*, but upon its surface in the trachea. There are many other similarities, but time does not permit them to be referred to.

As to when to operate, croup cases are divisible into two groups,—viz., those in which the dyspnœa is subject to violent exacerbations, but is slight during the intermission; and those which steadily increase, each paroxysm being succeeded by a relative intermission only, the dyspnœa steadily increasing. In the first class of cases the patient may, it is true, die in an access of dyspnœa, but there is time to try medical measures usually. In the second class, when there is marked depression of the epigastrium and base of the chest, and also of the episternal and supraclavicular fossæ, despite the persistent use of the admirable treatment suggested by Dr. Cohen, operate at once.

Personally, I prefer to operate without ether, although it is harder for the operator, unless the patient has become insensible from carbonic-acid poisoning.

The fenestræ generally found in the tubes I regard as ridiculous. They are generally to be found outside the trachea when the tube is in place.

There should be no hurry in doing tracheotomy. Both hurry and force are exceedingly dangerous, and kill the patient sometimes. A hurried operator may force down the membrane before the tube; the trachea, being more resistant, may be cut, while the membrane will give before the knife, if the latter has been dulled. Some form of dilution had better be used to permit the removal of loose membrane, etc.

[Subsequently Dr. Nancrede said, in answer to Dr. Stewart, "I am aware that diphtheria is a disease of asthenic character, but I deny that it always commences as such, especially in the larynx, and inquiry will often develop the fact that there has been an attack of pharyngeal diphtheria precedent to the croup."]

Dr. W. S. Stewart: I have been very much interested in hearing the discussion this evening. I remember hearing a paper read before this Society some time ago, in which the necessity of early operation in croup was urged. But the reader of that paper, when interrogated as to his success in his operation, had not had one recovery. In the paper of this evening there is a large proportion of recoveries. The contrast between the two papers reminds me of a little experience when I went with a brother physician, who had a subject, as he thought, necessitating an operation as a *dernier ressort* for croup; the parent of the child refused to permit the operation, as soon as the arrangements would be made; and so fickle-minded was he that three unsuccessful attempts were made to perform tracheotomy during an interval of two days, and still the child recovered without the operation. The difficult problem to solve is the mortality that would result from not operating, and the actual lives saved by operating.

I have no hesitation in maintaining that croup and diphtheria are distinct diseases.

I confess I have not had the experience of the last speaker in seeing a case of diphtheria develop and terminate fatally in a few hours. And I could not account for such results, except in the fact of its being an insidious development, and in its asthenic nature giving no special symptoms for a certain interval of time at first except the feeling of languor and an unaccountable sensation of lassitude. Croup, on the other hand, is a sthenic disease, is ushered in suddenly, and is always accompanied by a cough of a peculiar and characteristic sound. The membrane of croup is lighter in color than that of diphtheria, lies more on the surface of the fauces and trachea, and is more readily expelled by coughing, whilst the germs which enter into the formation of the diphtheritic membrane embed themselves within the tissue, and are of dusky hue, and with greater difficulty removed; it is not accompanied by a cough.

Dr. Jas. F. Stone: There is one point that I would like to emphasize, and that is the vital importance of attending the patient carefully after the operation. I am one of those who believe in the necessity and very great advantage of this operation, and in its early performance; and yet I do not believe it should be performed unless the physician will devote a proper proportion of his time to the after-treatment. When we consider that the operation is of a character that does not relieve the physician of his responsibility, but even makes it greater, we should be willing to devote days, and possibly weeks, to its proper performance.

Dr. Sajous: In a case which I saw to-day, operated upon by myself two weeks ago, I noticed that a peculiar odor accompanied each expiration, and, upon examination, found a spot of ulceration just opposite the fenestra (this being rather low down near the tracheal aperture of the instrument), upon the posterior wall of the trachea. I consider the fenestra as useless. The distance between the tube *in situ* and the wall of the trachea is sufficient for the passage of air, and when the voice can be used the tube does not offer enough interference to prevent the formation of the voice.

Dr. Formad: As to the misconception be-

tween croup and diphtheria; some gentlemen have expressed an opinion that there are different pathological processes in the two. Pathologists never asserted that the two diseases are clinically identical, but only that the pathological process is identical. If the product is different, it depends on the locality affected. We may have a urethritis or a cystitis; the diseases are different, and the symptoms different, but the pathological process is identical. It is nowhere said, in textbooks of pathological anatomy, that croup and diphtheria are clinically, or even anatomically, the same.

In diphtheritic angina the deposit is deeply seated because the inflammatory exudate cannot get outside on account of the anatomical construction of the mucous membrane of the pharynx. In the larynx and trachea the exudate cannot stay below, it being expelled by the elastic tissue of the mucous membrane, which, moreover, has but one layer of an easily-permeable epithelium. The exudate is bound to get out as soon as formed. We may have similar exudates in any surface of the body, in each case the deposits differing with the local conditions. Virchow has well expressed these differences: diphtheria is "eine Einlagerung," croup is "eine Auflagerung," of the exudate.

In croup the absence of constitutional symptoms is easily explained. While in diphtheritic angina the deposit is embedded into tissues rich in lymphatics and blood-vessels, and death ensues usually from absorption of septic materials, in croup the deposit lies on the outside of the body; death may ensue from stenosis of the larynx or trachea, but not from absorption of septic materials, as there are but few blood-vessels and lymphatics in this situation. The anatomical difference fully justifies a clinical differentiation. The deposit of the exudate is like a nail, which may lie on the table or may be driven into the wood. The nail is the same in each case, but is under different conditions and has different effects.

Dr. Crandall, in closing the discussion, said: Dr. Cohen has referred to Dr. Jacobi's low percentage of cures latterly. Dr. Jacobi doubtless operated as scientifically and skilfully in his later as in former cases. So also does Dr. Levis; yet he reports many failures. I do not lay claim to great scientific accuracy, but wish to demonstrate the importance of after-treatment. The children averaged from three to four years of age, and this made it easier of performance in the cases given. I saw one of these cases every two hours, the other every four or five hours, and believe success due to this. I also believe that physicians should be able to perform this operation whenever called upon. I am under many obligations to those who have assisted me, this evening, in establishing the differential characters of these diseases.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held November 20, 1884, FORDYCE BARKER, M.D., LL.D., President, in the chair.

Dr. A. C. POST presented a new hard-rubber syringe for injection of the bladder and abscess cavities.

THE SURGICAL MANAGEMENT OF RACHITIC DEFORMITIES OF THE LOWER EXTREMITIES.

Dr. V. P. GIBNEY read a paper with this title, and said that by the term surgical management he wished to convey the impression that mechanical appliances, as well as cutting instruments, were surgical means for effecting relief. Despite the teachings of gentlemen who practised osteotomy, he was convinced that the bulk of the profession was of the impression that it was not every case of bow-legs and knock-knee which demanded surgical interference. He therefore raised the question, What cases can be safely left to nature? If he should state that many children recovered from deformity without any treatment whatever, he would be met by the statement that they did not have true bow-legs or knock-knee. The author then gave the definitions of these terms by Macewen, Little, of London, Poore, of New York, and others. But it was well understood by practitioners what was knock-knee, and it was his strong conviction that a fair proportion of knock-knee in children in the United States made a spontaneous recovery.

From 1871 to 1877 he saw at the Hospital for the Ruptured and Crippled two hundred and fifty-five cases of genu valgum in children under fourteen years of age. This represented a period when the apparatus for the relief of the deformity was theoretically inoperative, although practically it seemed to be of benefit. The patients wore the springs from six to eighteen months, and in nearly all the limbs were restored to their normal condition. Another reason for believing that many spontaneous recoveries took place was the scarcity of cases in the adult in this city. The large majority of osteotomies in this city were upon children from three to eight years of age. From 1871 to 1877 he saw only eighteen cases in patients between fourteen and twenty-one years of age, and only three in patients over twenty-one. Of the entire number treated at the hospital, two hundred and seventy-six, only fifteen were not cured, and these fifteen occurred among the twenty-one cases over fourteen years of age.

As to bow-legs, during the period of seven years prior to the introduction of osteotomy he saw at the hospital one thousand and five cases, nine hundred and ninety-seven of which were in children under fourteen years of age. He saw only three in adults, and

five in persons from fourteen to twenty-one years old. The large proportion of the nine hundred and ninety-seven came under treatment, and a good proportion never carried out the same. Their ages ranged from two to four years. Either the apparatus was very efficient or the limbs became spontaneously straight. The large majority of those operated upon in this city since 1879 doubtless were under seven years of age. It was very rare to see an adult American affected with bow-legs.

In answer, therefore, to the question, What cases should be left to nature? Dr. Gibney said that children under two years of age presenting bow-legs or knock-knee should not be subjected to apparatus or mechanical treatment unless the deformity be very exaggerated. Children under three years of age, with only a moderate degree of deformity, could, in his opinion, be safely left to nature.

In bow-legs we often had a general curve extending from the perineum to the ankle without any sharp deviations whatever, and again in many cases there was a sharp curve in the tibia and fibula at the junction of the lower and middle thirds. In the former cases he rarely found it necessary to employ any form of apparatus, while in the latter he rarely omitted to order an apparatus.

Knock-knee and bow-legs being more or less due to rickets, diet and general hygiene had much to do in the treatment. Many cases were cured on being sent to the country. Phosphates of lime and soda only acted upon digestion.

He practised manual force in these cases if the patient's parents were unable to buy apparatus, or were too improvident to give attention to its care, and in cases where one had little time in which to effect a cure; also in cases in which the bones would yield to the force, the other two conditions being present.

The author quoted with approbation from Macewen, who said that it might be safely concluded that *ostéoclasie manuelle* had served its time and could not be practised in the presence of the more exact methods of to-day. Among the more enthusiastic advocates of gradual correction of these deformities by apparatus was Little, of London. Even surgeons who favored osteotomy admitted that the age at which the bones yielded to force was the age for the use of springs. His own rule was to employ manual force if the bones would comparatively readily yield thereto. If he found the femur curved and the inner condyle unusually long in a case of knock-knee, he tested with his hands the ligaments of the knee and the femoral curve, and was guided in his selection of cases for the use of an apparatus. The age beyond which this test failed was from four to five.

All the springs now in use were constructed on one principle,—namely, to bring force to bear against the convexity at its apex. One class of springs was intended to exert moderate but continuous pressure, while another exerted momentary pressure. Of the latter method Dr. Shaffer was an advocate.

Osteoclasis certainly had not become popular in the United States, notwithstanding the excellent results obtained with it by Robin, of Lyons, and others across the ocean.

As to osteotomy, Macewen stated at the International Medical Congress at Copenhagen that, out of eight hundred and twenty personal cases of supra-condyloid osteotomies, there were only eight cases in which suppuration occurred; hemorrhage occurred in one case. Five died, but death was not due to the operation.

Dr. Gibney remarked that he had never seen an anterior tibial curve corrected by an apparatus. During the past six months he had performed nine linear and two cuneiform osteotomies at the Polyclinic, sending the patients home as soon as the plaster of Paris hardened, and in none had the temperature risen above 102° F. In one case of supra-condyloid osteotomy there subsequently occurred paralysis of the external peroneal nerve of two months' duration, due probably to callus.

From his operations Dr. Gibney had learned the following lessons: first, exaggerate the correction of the deformity; second, examine the limb at the end of a week, to ascertain whether the amount of correction gained was the amount desired; third, do not hesitate to refracture by manual force if it be necessary; fourth, with strict attention to details in operating and in the use of good plaster-of-Paris bandages well applied, cases could be treated in dispensaries nearly as well as in hospitals; fifth, in dispensary cases do all the operating at one sitting.

Dr. Gibney was still convinced that one lost nothing in observing Listerism as closely as possible.

DISCUSSION.

Dr. JOSEPH D. BRYANT agreed with the author of the paper, that many cases recovered spontaneously. He referred to the alleged causes of bow-legs, as weight of the body, muscular contraction, sitting with the legs crossed. The fact that many cases did not recover if left untreated raised the question whether any cases ought to be left to nature. Much was to be gained by good hygienic management. As to treatment, if he found the bones springy, he applied force to the greatest angle of convexity two or three times weekly. He believed, with Dr. Gibney, that every case which could be affected by moderate, or even a greater, degree of force, was suitable for treatment by an apparatus, and he favored a spring which was not sufficiently powerful to do injury to the soft parts. Osteoclasis had been used but little in this city, and he would not be willing to apply it near the joint. He looked upon

osteotomy as one of the most important branches of surgery during the present century, especially if combined with antisepsis. He had yet to experience any ill result following the supra-condyloid or tibial operation. He had not even had a drop of pus associated with the operation. He related a case illustrating the advantages of antiseptic precautions. The oldest patient upon whom he had performed the supra-condyloid operation was sixteen years of age, and in that instance there was a temperature of 102° on the third day, and later another slight increase, but no local condition was the apparent cause, and the patient made a good recovery.

Dr. C. T. POORE would confine his remarks to a few points. First, it seemed to him important to know what was the exact pathological condition back of knock-knee, otherwise we would have no good basis for treatment. There were many cases in which there was apparent knock-knee, but in which there was no real bone lesion. In all cases in which there was a bone lesion, the cause he believed to be rickets. Traumatic cases were excepted. That being true, what should be the treatment? There was no question that in the early stage of rickets, before consolidation had taken place, the bones could be bent. He could not understand, however, how the limb could be straightened by mechanical force after consolidation had taken place. Dr. Gibney had seen spontaneous cure from knock-knee of true bony origin, and his word was to be accepted without question, but Dr. Poore thought the cases could not be numerous in which a cure was effected without treatment; at any rate, he had not seen any. He thought knock-knee of rachitic origin was much more common now than a few years ago in this city, and the fact that there were but few adults suffering from the deformity was due to the comparative freedom from the affection in this country. If taken in time, the cases could be successfully treated by properly-applied splints. If no benefit followed after a certain length of time, he could not see what further was to be gained by the continued use of splints. If you could not correct the deformity while the bone was soft, you certainly could not after it had become hard. The age at which the bone became hardened was a question of nutrition, and varied in different children. After the bone had become hard an operation was called for. As to osteotomy, he would add nothing to what had been said by the author of the paper, except that in most of the cases in which hemorrhage had occurred this might have been avoided. He had never kept a patient in bed more than five weeks. His rule was to remove the plaster of Paris on the fourth week, and within a few days the patient would be out of bed. He had never had a recurrence of the deformity.

With regard to osteoclasis, he thought it far better in bow-legs than manual force, as the fracture could be produced at any desired point if sufficiently far from the malleoli. He had never seen any accident of any kind result from osteoclasis, nor had he ever failed to correct the deformity. He thought long curves were better treated by osteoclasis, while short, angular curves near the epiphyses and anterior curves were better treated by osteotomy. He did not employ Listerism, strictly speaking.

Dr. M. H. HENRY said that for many years at the Immigrants' Hospital they had many children of foreign birth. There were few Italian children who suffered from deformity of the lower extremities. Most of those who were deformed were rachitic, and, with better diet, better bedding, and better clothing, they almost invariably recovered with little or no surgical treatment. The limit of their stay at the hospital on the island was five years.

Dr. M. JOSIAH ROBERTS, in speaking of the comparatively few cases of bow-legs and knock-knee in the adult in this city, said it should not be forgotten that the death-rate in children was greater than in more mature life, and this was especially so among those suffering from a constitutional dyscrasia. Moreover, recovery from these deformities was not usually absolute, but one of degree. He could point out many cases of bow-legs of moderate degree among the pedestrians of Fifth Avenue, and it would be found that persons thus deformed were incapable of prolonged locomotion or of standing for a considerable period of time. While he agreed with the author of the paper that there were many spontaneous recoveries, he wished to emphasize the fact that many cases of so-called complete recovery were recoveries only of degree. He showed photographs in illustration of this statement.

Dr. Roberts differed from the author in the view that the deformity in bow-legs pertained to the entire limb. Photographs of the bones with the flesh removed showed that the shaft of the femur and tibia was nearly or quite normal in shape, and that the deformity existed rather in the joint and the junction between the epiphysis and diaphysis.

As to what cases should be left to nature, while he believed with the author that many cases recovered spontaneously, he thought the surgeon could aid nature in every case, and shorten the period of cure. Manual force had a very limited application, being justifiable only in cases in which the bone was quite soft. There were different mechanical appliances which had proved of benefit, and among others was one by Dr. Davis, the founder of orthopædy in America, a description of which the speaker gave. He also called attention to the importance of instruments of precision in determining the exact degree of the deformity, and said that

without such measurements a general statement of a surgeon that his patient had entirely recovered was not of much value.

Dr. Roberts regretted that the author had not dwelt longer upon the subject of the best means for doing osteotomy. This question could not be considered as settled so long as surgeons continued to employ chisels for the division of hard bone, which, under the most favorable circumstances, was very difficult to divide in this manner, and, in the living subject, involved danger to the soft parts. He then described his electro-motor, the cutting apparatus consisting of a circular saw, which could be made to divide the hardest and largest-sized femur within three seconds. By protecting the soft parts with broad retractors, the most bungling operator could not do any injury with the instrument.

Dr. HOPKINS referred to a case of exsection of the knee-joint for knock-knee not of rachitic origin.

The PRESIDENT inquired as to the influence of sex as affecting the frequency of rachitic deformities of the lower extremities, and also as affecting spontaneous cure. He asked the question because it had often occurred to him to have anxious mothers express great solicitude for their little girls affected with bow-legs.

Dr. GIBNEY, in closing the discussion, said that, so far as he could recollect, the figures at the Hospital for the Ruptured and Crippled showed about an equal number of cases in the two sexes, with about an equal number of spontaneous cures. A great many women who had suffered from bow-legs during early childhood would be found to have flat-foot. He thought a good many of the adult cases seen in this city were not cases of knock-knee of the kind treated of in this paper, but occurred in stout men, and were of an atonic type, as described by Little.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

AN adjourned annual and a stated meeting were held November 24, 1884.

The retiring President, Dr. S. O. VAN DER POEL, read his address, in which he referred with approbation to the amount and quality of the work done by the Society during the past year, to the large increase of membership, amounting to one hundred and twenty-seven additional members since the last annual meeting, and returned his heartfelt thanks to the Society for the uniform courtesy which he had received at its hands during his term of office. He recommended that essayists seek to elucidate some particular point, either controverted or in need of fuller investigation, in the large field of medicine, and that those who partake in the discussion make their remarks relevant to the questions raised in the paper, and present their views in concise language, thus avoiding the emptying of benches by rambling debate.

The President for the ensuing year, Dr. DANIEL LEWIS, then called the stated meeting to order, and, after paying a eulogy to the retiring President, Dr. Van der Poel, and promising to advance as far as possible the interests of the Society which had conferred upon him the honors of its chief office, referred to the importance of all physicians who wished to take part in framing laws relating to the medical profession in the county and State joining the county medical society, and said that the law of 1880, regulating the practice of medicine in the State of New York, had proved far more reaching and effective than even its framers had anticipated. The necessity for a State Medical Examining Board was obvious as a means of suppressing quackery and promoting a higher grade of medical education. Such a board, however, should it be organized, as it was probable it would be in the near future, should have power to revoke a license to practise, if sufficient grounds for doing so were presented. He also thought it might add to the scientific interest of the meetings if the gentlemen expecting to take part in the discussion of any given paper would send their names to the Secretary, that the fact might be made known on the cards of announcement. He recommended timely measures against the possibility of an epidemic of cholera. The donation which the College of Physicians and Surgeons had lately received from Mr. Vanderbilt would probably soon lead to a change of location of that college, and he therefore thought it advisable that the Society procure at an early date another hall in which to hold its meetings.

Dr. Lewis then announced the following members of committees for the ensuing year: On Hygiene, Drs. Stephen Smith, Alexander Hadden, E. H. Jones, Cyrus Edson, William L. Hardy; on Ethics, Drs. George A. Peters, W. T. Alexander, Mark Blumenthal, C. C. Lee, Edward Waitzfelder; on Prize Essay, Drs. F. R. Sturgis, Frank P. Foster, W. R. Birdsall; on Auditing, Drs. P. Albert Morrow, Gorham Bacon.

On motion of Dr. VAN DER POEL, that portion of the address relating to obtaining a suitable hall for the Society was referred to the comitia minora.

ON THE THIRD STAGE OF LABOR.

Dr. SIMON BARUCH read a paper with this title, and said that his reason for so doing was that experienced and learned obstetricians were still at variance as to the proper method of conducting the third stage of labor. He then briefly referred to the common division of labor into three stages,—the first, second, and third,—which he accepted. In general terms, it might be said that, in proportion

as labor advanced, was any deviation from the normal processes dangerous to the mother. With the advent of the third stage, the patient was ushered into a condition in which the perils from abnormal processes culminated. Here attention to details which in themselves might seem insignificant was all-important for the preservation of the woman's health and preventing the destruction of human life.

There were three methods of dealing with the placenta in vogue at present. The first was the ancient method of pure expectancy; the second method consisted in active assistance in the removal of the placenta, and had as outgrowths the Dublin, and later the Crédé, methods; the third, or eclectic, method occupied a middle ground between the extremes of expectancy and energy of procedure. The author thought that in this department of medical art, as in all other departments, the golden mean was to be desired. He then quoted the views of various authorities, European and some American, with regard to the value of these several methods, particularly the expectant and Crédé's, and showed that many of those who professed to practise Crédé's method failed to do so in fact. Reliable statistics of cases treated according to the expectant plan and the method practised by Crédé showed the advantages of the latter.

It probably has been the experience of every obstetrician to have met with cases in which the placenta has been retained within the vagina, perhaps, for two hours without doing any harm, but it seems unreasonable to maintain that it was of any advantage to have the membranes retained for a length of time in this locality. The author had had but a single case in which the placenta had been unduly retained within the uterine cavity. He thought that many lives had been lost by waiting for the uterus to expel the placenta of its own accord after an abnormal and a protracted labor. Every case should be treated according to its own peculiar surroundings. It could be of no advantage to leave a woman lying hour after hour in her own gore, in anxious suspense and great discomfort, waiting, with the idea that we are giving nature fair play for the expulsion of the placenta. The eclectic method seeks to make use of all the advantages possessed by Crédé's, while omitting any of those measures which it might be well to discard.

The author then referred to the twofold power of contraction possessed by the uterus, the one being tonic and the other clonic. The latter alone constituted a true uterine pain. The former was illustrated during uterine involution after delivery. These clonic spasms for the expulsion of the placenta, or the third stage of labor, might be modified and rendered more or less abnormal by one or more unnatural conditions, as social surroundings, peculiarities in the second stage, the use of chloroform during labor, the tendency to hemorrhage.

The author spoke of his experience in midwifery among the colored people of the South as compared with that among the higher classes of the metropolis. In the woman of high social position many hours usually passed in what were called preparatory pains, and by the time the second stage had been reached the nervous system was in a high state of reflex irritability, the expulsive contractions were not so steady and forcible; and here the author believed existed a cause of rupture of the perineum, as during the last four years of his obstetric practice, which had been in the city, he had seen more cases than during his fifteen years' previous practice in the South. In the negress he often found the placenta expelled into the vagina very soon after delivery of the child, while this was seldom the case in the city woman. In the latter class of cases haste in the third stage of labor was strictly to be avoided; perfect rest under proper surveillance was the true course. Injudicious friction or pressure would cause undue uterine irritability and fail of the desired object,—viz., to obtain strong expulsive contraction.

The fact that chloroform had been given indicated that the uterine powers had been reduced; clonic contraction-power of the organ, which was necessary for the expulsion of the placenta, had been diminished. He would therefore recommend that the anæsthetic be diminished as the third stage was approached, and that Crédé's method be aided by the Dublin method of following the uterus down with the hand. When there was a tendency to hemorrhage, Crédé's method alone could not be relied upon: the uterus should be followed down as the child receded from its cavity, and should not be permitted to pass from under the hand. The method which he adopted, doubtless, was that practised by many other physicians, consisting in gently stroking the uterus to stimulate it to contraction, of grasping the uterus with the outspread fingers, intensifying the strength of the contraction, and making downward pressure for the purpose of aiding in expelling the placenta out of the vagina or vulva. It might be necessary, in some cases in which the placenta was grasped by the neck of the uterus, to make traction upon the cord, or to insert the disinfected fingers and make direct traction upon the placenta itself. It was his custom to place the two fingers of the right hand within the vulva, while the uterus was being compressed with the left hand, in order to guard against too forcible expulsion and rupture of the membranes. The author regarded twisting of the membranes as objectionable, as it was liable to excite too energetic contraction and rupture of the membranes.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held November 26, 1884, GEORGE F. SHRADY, M.D., President, in the chair.

OS COCCYGIS REMOVED BY OPERATION.

Dr. JOHN A. WYETH presented the coccyx which he had removed from a man, 36 years of age, who four years ago sustained an injury by falling backwards on the ice. No symptoms were noticed at the time of the fall, but a few months later the patient was seized with spasm of the sphincter ani muscle, which condition grew worse and led to two operations for fissure of the anus, the first operation being by the knife and the second by stretching of the sphincter. Dr. Wyeth recognized displacement of the coccyx by the fact that the stools were flattened and grooved, evidently due to some obstruction. Later he operated upon the same patient for inguinal hernia by Heaton's method. The patient was still a monomaniac, but Dr. Wyeth thought there would finally be entire cessation of the symptoms.

MODIFICATION OF OTIS'S URETHROTOME.

Dr. WYETH also presented Otis's urethrotome, which he had so modified that, when cutting through even the densest tissue, the extent of the incision could be restricted within absolute limits.

Dr. PEABODY had, during the past summer, removed the coccyx in a case of coccygodynia without giving relief to the symptoms, but the woman was afterwards cured by measures directed against neuralgia.

Dr. J. P. GARRISH had cured the symptoms in several cases of injury to the coccyx by dividing the nerve-supply along the surface of the bone.

Dr. W. M. CARPENTER said that Dr. Goodell, after operating upon cases due both to injury and to neuralgia, had reached the conclusion that in cases of coccygodynia the operation which promised the best results was removal of the bone, whereas in essentially neuralgic cases anti-neuralgic measures might be resorted to.

PULMONARY GANGRENE IN PNEUMONIA.

Dr. L. E. HOLT presented the lungs removed from the body of a boy three years of age, who died after two weeks' illness with pneumonic symptoms. The child had always been very healthy, and had never had any sickness except a bronchitis at the first year of age. At the autopsy a sacculated pleurisy containing turbid fluid was found over the middle of the right lung behind. Both lungs were strongly adherent to the chest-walls, the right one particularly so. There was extensive formation of new membrane over the entire surface of the right lung. The upper lobe showed only congestion and œdema. The upper portion of the lower lobe presented the usual gross appearances of broncho-pneumonia. Over the base were two large, irregular areas, dark in color, grayish at the borders, and in the centre gangrenous spots were found, varying in size from a walnut to a pea. The interior could be washed away with a moderate stream of water. There was no marked separation between the necrotic and the living tissue. The areas of gangrene did not correspond to the distribution of the pulmonary artery, but to that of the bronchi. The bronchi were much inflamed. The heart was normal. The kidneys were enlarged, light in color, soft, the markings indistinct. There was nothing to attract attention to the urine during life, but that found in the bladder after death was found to contain albumen and casts. Dr. Holt was not inclined to think there was any connection between the occurrence of gangrene in the lung and the disease of the kidneys. He quoted the literature of gangrene of the lung occurring during the course of pneumonia, and said that such cases were very rare indeed, and were found less frequently in children than in persons more advanced in years. The autopsy had been made by Dr. Northrup.

UREA NOT A CAUSE OF URÆMIA.

Dr. G. L. PEABODY said that at the last meeting of the Society he had expressed the opinion that too much stress had been laid upon urea as a cause of uræmia, his opinion being based more or less upon observations in the lower animals. Dr. Seguin had been of a similar belief, but spoke of experiments recently made in which it would seem that uræmic symptoms might be induced in lower animals by injection of urea into the blood. Dr. Seguin had since informed Dr. Peabody where he could gain access to the records of the experiments to which he had referred, and Dr. Peabody took occasion to show to the Society that it would require, according to the amount of urea necessary to produce death by injection into the circulation of the dog during these experiments, one pound and a half of urea to produce a fatal result in man. But it had been shown that in a man of one hundred and fifty pounds weight, dying of uræmia occurring in the course of kidney-disease, the blood contained only nine-thousandths of one pound of urea. There might be apparent fallacies in this manner of drawing conclusions, but he thought it showed very conclusively that such experiments upon animals could give us little useful information as to the cause of uræmia in man. The injection into the blood of benzoate of soda or of sulphate of soda, agents which were not in themselves poisonous, would likewise produce uræmic symptoms. The experiments quoted went no further than to show that the injection of a certain amount of any foreign substance into

the circulation would produce death; they did not show that uræmia was due to the presence of urea in the circulation. He had seen several cases in which there had been entire suppression of the urine, terminating fatally, in which there had been none of the so-called uræmic symptoms.

ABSCESS OF THE LIVER WITH OBSCURE SYMPTOMS.

Dr. PEABODY also related the history of a case and presented specimens, there being certain indefinite symptoms leading him to suppose that the man had once had typhoid fever and that his last illness was due to a relapse of that disease, but the autopsy showed two abscesses of the liver, the larger containing half a pint of pus. There were also ulcers of the large intestine. The stools during life had presented the ordinary appearance of stools after the taking of compound cathartic pills, which the patient had received for constipation.

SARCOMA OF THE KIDNEY.

Dr. FRANK FERGUSON presented a kidney, the seat of sarcoma, supposed to be congenital, removed by operation from a child four years of age. The history of the case had already been put on record by Dr. Little.

Dr. FERGUSON also presented a tumor of the first phalanx of the right ring-finger, which followed an injury, and containing a large number of so-called giant cells.

In reply to a question by Dr. WYETH, Dr. PEABODY and Dr. NORTHRUP said that it was very seldom that a case of congenital sarcoma came under observation.

RUPTURE OF ANEURISM OF THE ABDOMINAL AORTA.

Dr. G. A. DIXON presented an aneurism of the abdominal aorta removed from the body of a woman, 26 years of age, who was admitted to the hospital November 18 and died on the 21st. Her father died of phthisis, and her brothers and sisters died young. There was no history of syphilis. Since last spring she was treated in St. Luke's Hospital for femoral aneurism, which was reduced by pressure, and she was discharged cured. Three months ago her courses ceased, the appetite failed, there was nausea and some vomiting. A month ago the patient noticed a lump in the abdomen which pulsated. On examination, the patient was weak, anæmic, constipated; vomited a great deal; could not sleep because of pain. Physical examination revealed a systolic heart-murmur, a pulsating tumor in the epigastric region, the seat of a distinct impulse occurring with the second sound of the heart. The tumor had a marked thrill, with a double bruit. The patient died in collapse. At the autopsy was found an aneurism of the abdominal aorta, near the cœliac axis. Nearly the entire wall of the aorta was involved in the sac, and anteriorly was a rupture about half an inch in circumference. Above the aneurism was an atheroma, and below a constriction of the vessel scarcely admitting the little finger.

FIBROID TUMOR OF THE UTERUS.

Dr. H. C. COE presented two uteri with fibroids, removed by abdominal section.

GLEANINGS FROM EXCHANGES.

PAPAYOTIN is the active principle of the juice of the melon-tree (*Carica Papaya*, L.), native of the tropical zones, and flourishing especially in Brazil, where it only requires about six months to grow to a man's height and to furnish fruit which ultimately attain a weight up to fifteen pounds.

After three years, when the tree is about eighteen feet high, and about a foot in diameter, it begins to die off from above downwards. Up to this period, however, it is very fruitful, there being no period of the year when it does not bear either flower or fruit. The wood contains an abundance of yellow, rather bitter milky juice, which possesses in a high degree the property of digesting albumen, and therefore also meat, similar to gastric juice. It has, moreover, the remarkable property of not confining its digestive action to acid solutions, as is the case with pepsin, but it is equally active in neutral or alkaline solutions.

The French chemist Wurtz, in conjunction with Bouchut, first extracted the digestive ferment, *papayotin* or *papaïn*, in 1880. Bouchut employed it in the Child's Hospital in cases of dyspepsia and other disturbances of the digestive organs for which pepsin had previously been used, and obtained the best results. Rossbach found that the substance was capable of rapidly dissolving and removing the membranes forming in croup or diphtheria, and thereby greatly contributing to a favorable termination of the disease. It is assumed that by the "digestion" of the diphtheritic membranes and the morbid elements probably existing in them the further introduction of the latter into the blood is prevented. But it will require further study to fully clear up its method of action and its value as a remedy in these diseases. (It is applied by brushing over the diphtheritic spots a solution of the substance.) It is, however, important that only a reliable preparation be used, since there are some in the market which are quite inert. (Dr. W. Fliess, in *Pharm. Zeit.*)—*American Druggist.*

A CASE of fracture of the penis in a young and healthy man, with complete recovery, is reported by Dr. Veazie in the *New Orleans Medical and Surgical Journal* for October.

MISCELLANY.

COCAINE IN DENTISTRY.—In an article in the *Dental Cosmos* for December on the "Hydrochlorate of Cocaine," the new local anæsthetic, the author, Dr. Howe, speaks enthusiastically of his experience with it in filling teeth. The application of a few drops of a two-per-cent. solution upon cotton placed in the cavity of a tooth will reduce the sensitiveness of the dentine so as to permit cleaning and filling with practically no pain and but little discomfort.

THE BIOLOGICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA was formally opened on the 4th instant by Provost William Pepper. Addresses were made by Drs. Harrison Allen and Joseph Leidy. The Faculty of this Department is constituted as follows: William Pepper, M.D., LL.D., Provost of the University and *ex-officio* President of the Faculty; Joseph Leidy, M.D., LL.D., Professor of Anatomy, Director of the Biological Department; Joseph T. Rothrock, M.D., B.S., Professor of Botany; Harrison Allen, M.D., Professor of Physiology; Andrew J. Parker, M.D., Ph.D., Professor of Comparative Anatomy; Horace Jayne, M.D., Professor of Vertebrate Morphology; Benjamin Sharp, M.D., Ph.D., Professor of Invertebrate Morphology; N. Archer Randolph, M.D., Instructor in Physiology. Further details will appear in the next issue of the *Times*.

DEPARTMENT OF PHYSICAL EDUCATION AT THE UNIVERSITY OF PENNSYLVANIA.—On the 2d instant the Trustees of the University added a new department to those already in existence, and elected Dr. J. William White Director, with a place in the College Faculty and the title of professor. It is intended to model the new institution upon that of Harvard at Cambridge. The sum of fifty thousand dollars will be required for a gymnasium, of which ten thousand has been subscribed by the athletic department of the University.

NEW PROFESSORS.—Dr. Edward T. Bruen has been elected Professor of Physical Diagnosis, and Dr. Louis Starr Clinical Professor of Diseases of Children, in the University of Pennsylvania.

NOTES AND QUERIES.

FREIBURG.

TO THE EDITOR OF THE PHILA. MEDICAL TIMES:

DEAR DOCTOR,—In the *Philadelphia Medical Times* for August 23, 1884, I published a communication "Concerning Student-Life Abroad," and to the few remarks made concerning the University of Freiburg in Baden I would add an extract from a letter just received from Prof Baumler.

What I said about Freiburg and its advantages for health and opportunities for the deepest study was not overstated, and I sincerely hope that some of my countrymen may make that town a visit and become members of its ancient and honorable medical department. There are few places in Germany where better and more profitable work can be done. The student, native or foreign, has exceptional advantages there, and, the living expenses being very reasonable and the climate very healthy, I always urge the claims of Freiburg as of primary importance. I have in the communication referred to explained my reasons for so doing. Professor Baumler writes as follows, and I may say that by his own faithful efforts he has contributed not a little to the success of the improvements made:

". . . We try to do our best to further our university, and if you came here now you would find the hospital vastly improved, a new chemical laboratory, a new house for pathological anatomy and experimental pathology. A clinic for mental diseases, which will contain eighty beds, is going to be built immediately, and the newest addition to our laboratories will be one for zoology and comparative anatomy, under our celebrated zoologist, Weisman. . . .

(Signed) "CHRISTIAN BAUMLER."

It is very fortunate for the foreign student that Prof. Baumler is so kindly disposed to assist all who come in his way, and his distinguished position and time fully occupied show the generosity of the learned professor's character. With my best wishes for Freiburg and the faculty, I am

Very truly yours,
W. THORNTON PARKER, M.D.

ATLANTIC CITY, NEW JERSEY,
December 2, 1884.

OBITUARY.

PROF. SAMUEL M. BEMISS, M.D., of the Tulane University of Louisiana, on November 18 died suddenly of apoplexy, at his home in New Orleans, in the 64th year of his age. He was a man of distinguished attainments, of noble character, and of great social qualities. His loss is mourned as a public calamity.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM NOVEMBER 23, 1884, TO DECEMBER 6, 1884.

IRWIN, B. J. D., MAJOR AND SURGEON.—Granted one month's leave of absence. S. O. 112, Department of Arizona, November 28, 1884.

O'REILLY, ROBERT M., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty as attending surgeon, Washington City, D.C., to date from October 20, 1884. S. O. 284, A. G. O., December 4, 1884.

LORING, LEONARD Y., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty as post surgeon, San Diego Barracks, San Diego, Cal. S. O. 135, Department of California, November 19, 1884.

BARROWS, C. C., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—In addition to other duties, to take charge of Medical Director's Office, Department of Arizona, during absence of Surgeon B. J. D. Irwin. S. O. 112, Department of Arizona, November 28, 1884.

WILSON, GEORGE F., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Granted one month's leave of absence, from November 20. (Vancouver Barracks, Washington Territory.) S. O. 180, Department of the Columbia, November 18, 1884.

KNEEDLER, WM. L., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Fort A. Lincoln, Dakota Territory, and ordered to Camp Poplar River, Montana Territory. S. O. 140, Department of Dakota, November 25, 1884.

PILCHER, JAMES E., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—To be relieved from duty at Camp Poplar River, Montana Territory, and ordered to Fort A. Lincoln, Dakota Territory. S. O. 140, Department of Dakota, November 25, 1884.

WALES, PHILIP G., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Now at Fort Cœur d'Alene, Idaho Territory, ordered for temporary duty at Vancouver Barracks, Washington Territory. S. O. 179, Department of the Columbia, November 17, 1884.

MCCAW, W. D., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Fort Wingate, New Mexico, and ordered to Fort Lyon, Colorado. S. O. 228, Department of Missouri, November 26, 1884.

GRAY, CHAS. C., MAJOR AND SURGEON (retired).—Died at Geneva, N. Y., November 26, 1884.

NAVAL MEDICAL OFFICERS.

There were no changes in the Medical Corps of the U.S. Navy from November 23 to December 6, 1884.

PHILADELPHIA, DECEMBER 27, 1884.

ORIGINAL LECTURES.

CLINICAL LECTURE ON SUBACUTE BRONCHITIS IN CHILDREN.

Delivered at the Philadelphia Hospital

BY JOHN M. KEATING, M.D.,

Visiting Obstetrician to the Philadelphia Hospital, and Lecturer on Diseases of Women and Children.

Reported by WILLIAM H. MORRISON, M.D.

GENTLEMEN,—I shall, in the first place, bring before you a case which you saw some weeks ago, in order to show you the results of treatment. This child, as you will remember, is about 18 months old, and came into the ward in a very wretched condition. At that time I gave you a complete demonstration of the physical signs which were present. The child had been neglected before being brought to the house, and was at that time suffering with bronchitis of a subacute type. The treatment I then recommended was pursued. For some time the child did not seem to improve. At the same time, he did not seem to lose ground. Afterwards improvement gradually began, and the child is now much better than when you last saw him. It shows that, with proper care, children in even as low a condition as this one will pull through. This is, of course, more apt to occur in private practice than in hospitals. There was scarcely any fat on this child's bones when it was admitted, but now the chest has become much fuller, and the arms and limbs have grown larger. Its expression of countenance has also improved.

The treatment has consisted in the daily rubbing with a liniment containing cod-liver oil. It also received an emulsion of cod-liver oil, one-fourth of which was composed of the oil. To this was added Lugol's solution of iodine in the proportion of one drop to each dose. Quinine suppositories have been used for their tonic effect.

One reason for bringing the child before you to-day was on account of the question which arises as to the reason of the rapid wasting in this case. As I told you, the rapid wasting in such a case as this might depend on tubercular disease. This was especially the case, as we heard that the mother had died of phthisis; also we had symptoms calling our attention particularly to the chest, and there was a probability of enlargement of the abdominal glands. One point which was absent in this case was the fever. This is rather important, for the fact that there was no fever in this case rather pointed to the absence of tubercular disease. The temperature was taken every night with the thermometer in the rectum,—which is the proper way of taking the temperature in children,—but no rise of temperature was observed. The bronchitis gradually disappeared; the pulse remained normal; food began to be digested. The diet consisted of milk and Valentine's beef-extract, which is used quite largely in this house. There has been no vomiting, no purging, and no extra amount of tympanitic distention of the abdomen.

The next question—that of syphilis—was carefully discussed, and we came to the conclusion at the time that, as far as symptoms and appearance were concerned, there was no reason to believe that it existed. But our suspicions were aroused, and they always should be in the wasting diseases of children. The child did not have "snuffles" when it entered the house. What it had at birth I am unable to say. There was no eruption, nor stains of one; no mucous patches. Nevertheless, the results of treatment point to a syphilitic taint, but one which does not involve the integument or mucous membranes.

It might be that the poison came from a long-existing disease in either parent, which had been modified and rendered latent by constitutional treatment or time, and thus appeared in the offspring, as you see it affecting the mesenteric and bronchial glands, checking bony deposit, perverting dentition, and interfering with circulation by minute gummy deposits.

Do you always find emaciation in cases of inherited syphilis? By no means, according to my experience. This I wish to impress upon you. Some of you may remember a case which I showed to the class last year, one year of age, which had very large gummæ on the back and on the thighs. The infant was remarkable for its size and appearance of health. My friend

Dr. Van Harlingen, who saw the case, pronounced it syphilitic. The child had never been sick a day, but had been born with a "cold," and its mother had previously miscarried, and gave evidence of specific disease.

One of the worst cases of constitutional syphilis that I ever saw in this house was well nourished,—indeed, stout for its age. I have often noticed this, and I believe that it constitutes a characteristic of children who are infected with a mild form of specific disease inherited from parents who have supposed themselves cured before marriage. I would ask you to bear this in mind should a robust and to all other appearances healthy infant be brought to you with obscure symptoms,—a persistent eczema, or rickets in the ordinary acceptation of the term,—it may be really either retarded ossification, or, possibly, osteomalacia.

I recently attended the autopsy of a child, and from the appearances determined that it was syphilitic. It was but a few months old. The child was well nourished, had well-rounded limbs, and its chest was well covered with fat. It died from heart-clot, possibly caused by the pressure of enlarged glands. The heart-clot was enormous, greatly distending the right ventricle, completely shutting off the supply through the pulmonary artery. It extended through the jugulars and into the lateral sinuses. In the centre it was firm and of a chicken-fat color. The mesenteric glands were as large as grains of barley, some much larger; in fact, all the glands were enlarged.

The father afterwards acknowledged a hard chancre and palmar psoriasis many years before.

I am led to believe that the more we study these disorders from a clinical standpoint, the more we shall be impressed with the fact that many of the phases presented by the strumous diathesis are simply evidences of the presence of syphilitic virus, latent perhaps for many years in the father, transmitted by him to the offspring independent of the mother, and appearing at times when there is nothing to call our attention to it as a cause, and in so insidious a manner as to quiet suspicion. This is still a mooted question.

One feature has been well marked for some time. The child's head has become much larger. You will notice that the expression of its countenance differs from that ordinarily found. The eyes have a sort of upward look. The forehead, which projects, is somewhat square, and over it enlarged veins can be distinctly seen. The head also has a square shape. The veins are especially distinct over the top of the head. This marked prominence of the veins may be due to one of two causes. One is that, as the child is very much emaciated, and there being little fat, the veins are not covered up. Another reason is that the veins are distended. I think, in this case, the condition of the veins is not due altogether to the emaciation. There is a chronic venous congestion, which, taken in connection with the increased size of the head, which has been noted by actual measurement, would point to the fact that there is something distending the head and pressing out the bones. In fact, we have evidence of effusion taking place within the skull, producing pressure and expanding the head on all sides. Although this distention is not very marked, still it is sufficiently so to give you an idea of the appearance of a hydrocephalic head. Hydrocephalus, in these cases, is due, in all probability, to obstruction to the return of the venous circulation, especially at the base of the brain. In many cases it is due to thickening of the membranes at the base of the brain, which is the result of chronic meningitis, brought about, possibly, by tubercular deposit in the course of the small radicles of the arteries. This is usually the seat in which these deposits occur in children. Interference in the circulation of the veins then takes place, with congestion and consequent effusion. This effusion is generally found at the base of the brain and in the ventricles.

There is not present in this case, as might be expected, marked protrusion of the fontanels. The fontanels have not yet closed. They are not depressed, as they were at first, as a result of the anæmia. The anterior fontanel is level with the bones of the skull; it still pulsates, but it does not bulge as in a case of marked effusion. In cases where hydrocephalus begins early, before the closure of the fontanels, we should have marked bulging if the effusion came on rapidly. This child's head does not seem to be growing in size now. The probability is that this condition is a part of the general

disturbance of the circulation and general anæmia, and that we have no real hydrocephalic condition.

Possibly syphilitic gummata have been deposited upon the radicals of the vascular system of the pia mater at the base of the brain, forming what to the eye would appear as a clouding of the surface. The effusion resulting, meeting with the least resistance from the unossified sutures and open fontanels, would gradually increase the size of the head and give it this shape.

Do not confound this condition with what is known as hydrocephaloid disease, or spurious hydrocephalus, a condition of affairs found usually in the exhausting diarrhœas of children, and called Marshall Hall's Disease. That is exactly an opposite condition from that which is present here. In the one there are symptoms of anæmia of the brain, produced by the exhausting discharges; in the other there are symptoms of anæmia of the brain, produced by obstruction of the circulation. Both are due to anæmia of the brain; in the one due to the exhausting discharges from the bowels, as in cases of cholera infantum and enterocolitis; in the other due to some interference of the circulation, as from basilar meningitis; as a result effusion takes place, and anæmia follows. The anæmia results not only from the interference with the circulation, but also from the pressure of the effusion. The symptoms in the two would be much the same. In the hydrocephaloid condition there is depressed fontanel, pallor, and diarrhœa. Where effusion is due to obstruction of the circulation, there is a bulging or a level fontanel.

This case would represent a case of true hydrocephalus,—*i.e.*, a condition where effusion has taken place within, and as a consequence there is venous stasis occurring in the brain as a result of the pressure and as a result of the interference with the arterial supply.

Suppose this child exhibited very marked evidences of rickets, what would be the result? So-called rickety bones do not contain the normal amount of calcareous matter, and as a consequence they are softer than natural. In these cases the sutures do not unite until late. If, in such a case, effusion take place within the cranium, it would produce separation of the bones and give the peculiar shaped head which is diagnostic.

There is another variety of syphilitic rickets affecting the skull, the so-called cranio-tabes, in which the syphilitic virus has prevented ossification in fœtal life. In such skulls the points of ossification are seen; the rest of the skull is composed of membranes only and bony deposit in striations.

There is another form of rickets that comes on in children of three or four months as an acute febrile affection, with inflammatory congestion of the bone-marrow, especially attacking the long bones at their extremities. It runs a definite course and terminates in more or less deformity of the skeleton, with the formation of ivory-like bone, more or less curved in accordance with the strains placed upon it during the first or soft stage by pressure or muscular tension. That disease I believe to be a neurosis.

We shall continue the treatment which has already been adopted. We shall add to it one remedy which I think will be valuable. We shall give small doses of nux vomica, in order to strengthen the heart's action and increase the force of the circulation. The cod-liver-oil emulsion and the quinine by suppository will be continued. We will also begin with iodide of potassium in half-grain and gradually-increasing doses with the milk. The diet now consists of condensed milk (I greatly prefer *peptonized* milk) and arrow-root, but as the child grows stronger it would be well to put it upon stronger food, as, for instance, oatmeal gruel. This will supply the phosphates, which are important in the treatment. This should be well cooked and made thin, given twice a day. It is important in these cases not only to order food which is theoretically the proper thing, but it is important to see that this is digested. There is no use giving oatmeal if it be not digested, absorbed, and assimilated. The starchy elements have to be converted into grape-sugar. This is done more particularly by the ferment of the pancreas. It is therefore desirable to give the meal in such a form that it can be readily acted upon by the digestive juices. In England a small quantity of malt is often added to the meal, the action of the malt diastase being to convert the starch into grape-sugar. This principle has been adopted in Liebig's food. In some preparations malted grain is incorporated with various forms

of meal, so that when the mixture enters the bowels it can be digested and the starch converted into glucose. Mellin's food is made on this principle, and is probably one of the best in the market. Horlick's food also is made in this way.

We shall put this child on small quantities of oatmeal, giving it at first once a day, well boiled, and with very little sugar added, so as not to give rise to lactic acid. While this is given, its effects upon the bowels will be watched.

I wish you to bear in mind that in this case the instructive point is in regard to the temperature. If this child's temperature had gone up every evening to 101° or 102°, or there had been evident hectic, the prognosis would have been unfavorable; but, as the child's temperature has remained normal, although the other symptoms were very severe, the chances are that it will pull through.

Case II.—Mulatto infant, aged one year. Brought in the house by its mother, who is a married woman with several other healthy children.

This child is in much the same condition as the first one was a few weeks ago. There are, however, some points in the case which, in contrast with the case we have just seen, require special study. It is still very sick, though much better than a week ago. Its mother, who is a hard-working woman, placed the child out to nurse, and it has, without her care, gotten into the condition which you see. As it is now quiet, I shall make the physical examination of the chest. There is no difference in the percussion-note of the two sides. One week ago the right side posteriorly showed marked percussion-dulness. This dulness remained for two or three days. To day it has almost entirely disappeared. We lose even the liver-dulness. This is due to the immense distention of the colon or stomach with gas. In cases so emaciated and run down as is this child, there is usually decomposition of the mucus in the alimentary canal, and this gives rise to a large amount of gas, which distends the stomach and bowels, filling up the abdominal cavity and encroaching upon the thorax.

In rickety children this is a serious matter, and, by distending the lower portion of the thorax, leads to the peculiar hour-glass shape which is so characteristic. Protracted distention of the stomach by gas may, and frequently does, cause a permanent dilatation of the stomach in children, which is obscure and difficult to treat, and may be fatal. Excessive tympany, succussion, and indigestion are the frequent symptoms.

The child breathes very naturally, both sides seeming to expand alike. There is no sudden jerk in the respiratory movement, and there seems to be no pain connected with the movements of the chest. No pain was caused by percussion. The temperature has not been elevated. There is no vomiting. Up to two days ago there was some cough, but since then it has disappeared. Its appetite is good, and it does not fret much during the day.

When I first saw this child, I found from its history that it had been neglected. It was extremely emaciated. It, however, presented no specially prominent symptom except the cough. On percussion, I found dulness of the whole right side of the back. On auscultation, exaggerated, puerile breathing was heard above, but feeble breathing at the lower parts. The voice did not seem to be directly beneath the ear, as it would have been if conducted by a solidified lung. There was therefore no pneumonia. Placing both hands on the chest, I found diminished expansion on the right side. This dulness on percussion amounted to flatness. It was not the dulness of pneumonia. I thought that, in all probability, it was due to fluid effusion, which, when it occurs in children who are run down, is usually semi-plastic in character. It is frequently found post mortem when it had not been suspected before death. I do not recall having ever seen a child thinner than was this one when it came in.

In this case the treatment was an energetic one of tonics and counter-irritation. We also used cotton wadding around the chest, for the purpose of keeping the child warm. Counter-irritation was especially applied over the portion of the chest where we found dulness on percussion. The child was given cod-liver oil, and it was rubbed with it. The result is that the deposit has entirely cleared up in the course of a few days. The effusion has disappeared, and at present the child presents no evident pulmonary trouble. The cough has also almost entirely disappeared. The temperature in this case is also normal. In this case I have totally failed to get any evidences of syphilis.

These cases are instructive ones. If you are called to such a case, you should see that the child is kept warm, that the circulation is increased, that the organs of digestion are encouraged, and that the excretory organs are active, so as to carry off the waste. If the case is treated in this way, gradual improvement will be noted from day to day. This case should get well if the treatment is carefully carried out. The treatment is similar to that adopted in the previous case. In a few days it will be well to give oatmeal.

An important item in these cases is to keep the skin active. Tepid baths of rock-salt water are of importance. The skin is rubbed twice a day with cod-liver oil. It is therefore important to see that the skin is thoroughly cleansed, in order that its function, which is to a certain extent supplementary to that of the kidneys, be not impaired.

ORIGINAL COMMUNICATIONS.

INFECTIOUS SORE THROAT.

BY HUGO ENGEL, A.M., M.D.,

Professor of Nervous Diseases and Clinical Medicine in the Medico-Chirurgical College of Philadelphia.

SOME authors contend that acute tonsillitis and diphtheria are caused by one and the same poison; others insist upon different pathogenic elements causing both diseases. It is possible that both views are correct, assuming that by acute tonsillitis two distinct maladies may be meant.

In my opinion there are two kinds of acute sore throat,—the catarrhal and the infectious. In the first abscess-formation in one or both tonsils is a common occurrence, while in the last pus never forms. Though the inflammation may be intense in the former, the mucous membrane affected never assumes the angry and dark-red, shiny hue which is usually met with, at least in severer and typical cases of the latter. Further, while in both the tongue is apt to be heavily coated, in the catarrhal form, after the coat has been thrown off, the tongue resumes its normal appearance; but in the infectious kind, after the incident mentioned has taken place, the tongue shows the same fiery redness as the throat, it being shiny, near to its point greatly resembling the strawberry-tongue of scarlatina, and evincing a tendency to dryness. Then, in this variety, the patient suffers from the beginning from a peculiar weakness and lassitude, phenomena which are never observed in the catarrhal or simple sore throat, be it acute and intense or not.

But what still more indicates their different nature is the following. The infectious sore throat frequently makes its appearance in a house where one or more other members of the family are affected with diphtheria; the same rheumatic symptoms and the same peculiar eruptions that characterize many cases of diphtheria also accompany the infectious tonsillitis, and we occasionally find albumen in the urine,—a fact which to my knowledge has never been observed in simple sore throat. But what struck me as most peculiar was the frequency with which women are attacked by an infectious angina, complicated by rheumatic symptoms and a skin eruption. It was this observation which induced me to write these lines.

As is probably the case in every large town of our Northern and Middle States, diphtheria and sore throat are prevalent in our city during the autumn months, more so than during the spring or at any other time of the year. My attention having been drawn but recently to the infectious character of angina cynanche, I refer in the following to my experience only during the past two years.

In the autumn of 1883 two, and this fall three, cases of the disease which I am about to describe came under my observation, either in my own practice or in that of medical friends calling me in consultation. These five cases happened in women, and, while I cannot contend that the malady is met with only in the female sex, in an experience of twenty years—if my memory is correct—I have not seen a single instance where a male person had suffered from it, and several colleagues, enjoying an extensive practice, on reflection admitted that they had made the same observation, since they came to think of it. To give rise to no doubt, I premise that by saying the disease has been noticed only in females I do not mean the infectious angina in general, but the peculiar form under which it made its appearance.

I shall not tire the reader with reporting the history of all five cases, but select only that of the most typical. October

16 of this year a lady, the mother of a large family, came under my charge. She was suffering from a mild case of pharyngeal diphtheria. On the 19th of the same month her eldest son was attacked by the disease in a graver form; on the evening of the same day his seven-year-old brother contracted a severe sore throat, without evincing at any time, though the parts were daily inspected with special care, the least sign of a false membrane; and on the 21st his two-year-old sister had the first symptom of the disease in its worst form,—nasal diphtheria. The last patient died on the ninth day of her illness, October 30, under all the symptoms of septic poisoning. No other member of this family became infected, and the patients all recovered except the little girl mentioned.

The day before the death of the child, on October 29, one of the two servant-girls, Lizzie D., æt. 20, commenced to complain of sore throat. I saw her in the afternoon, when she told me that the evening before, near six o'clock, she had been feeling chilly, and immediately after noticed a pain on swallowing. The pain she referred to the right side of her pharynx. During the night she had slept but little, having suffered "from a burning fever, great thirst, and much pain in her throat and neck." In the morning some amelioration of the symptoms had set in, the fever having left her to a great extent, and the pain having lessened in severity, and the thirst ceased. But soon after dinner the symptoms had resumed their former vigor.

On examination, I found the whole pharynx, especially the soft palate, uvula, and tonsils, greatly inflamed. They had an angry, dark-red, shiny look. But nowhere was any diphtheritic patch to be discovered. Her tongue was coated with a heavy, yellowish, cream-like fur. Temperature, 104.1°; pulse, 122. The skin over her neck, chest, abdomen, back, and arms was nearly of a uniform deep redness, about a shade darker than is generally observed in scarlatina, and in this redness a papular eruption resembling that of morbilli was plainly visible and sufficiently developed to give to the touch the sensation of roughness. Her face showed the same red tint, but without the papules; the palms of her hands were in the same condition, while their dorsal surface evinced the normal skin. Exactly at the crest of the ilium all eruption ceased, her lower extremities being completely free from any change in the normal appearance of the skin.

During the next two days these symptoms continued. Usually at 10 A.M., at 5 and near 8 P.M., the temperature, which during the rest of the time did not exceed 101.2°, suddenly ascended, reaching within ten or fifteen minutes the height of 104.4°, and remaining at that height for about one hour, though sometimes nearly two hours and more. Generally, before the increase of temperature set in, the patient complained of feeling chilly. During these afebrile hours the skin appeared normal, the pulse was lowered in its frequency to 90, and all pain ceased or nearly did so. During the same time the patient felt only weak, and evinced scarcely any other symptom of general malaise but that "her bones ached her." She felt inclined to talk, and had a desire for food, though she vomited almost everything which she swallowed. But the moment the increase of temperature commenced the erythema and the eruption at once made their reappearance, the pain in the throat and nape of the neck returned, the patient complained of the dryness in her throat, became listless, and scarcely replied to any question, moaning all the time; she suffered from severe thirst, and her pulse beat at the rate of 124 per minute.

On account of the heavy coating of the tongue, the nausea, and the vomiting, and also because experience had proved to me that vomiting, if induced by medicine, generally accelerates the cure of acute tonsillitis, I gave her on the second day a sufficient dose of tartar emetic to cause emesis. The next morning the tongue was clean, but evinced the same fiery redness as the throat, and at its point for about one-fourth of its length it had the so-called strawberry appearance, while at about its middle it felt dry. The other symptoms continued unabated, only the vomiting ceasing. But on the fourth day of her illness the picture of the malady somewhat changed.

The fever, still appearing at stated intervals, now lasted but half an hour, and was then followed by the most profuse perspiration, not acid in character. The patient, besides, commenced to complain of the most excruciating pains in her righ

shoulder. On my inquiry, I found that there had been no urine excreted for the last twenty-four hours. I therefore added to the other treatment, soon to be mentioned, a teaspoonful of the infusum digitalis every fourth hour. The next morning she again micturated, but the urine contained considerable albumen, no blood, but a few hyaline casts. I will here mention that two days later the excretion of the urine was normal and free from any morbid contents.

During all this time the patient had slept very little, and taken but fluid nourishment in very moderate quantity. Her bowels had to be moved by laxatives, but they responded very readily to their action. One-third of a bottle of a solution of citrate of magnesia, for instance, was followed by four loose stools of a greenish color and fetid odor. There was no pain in the right iliac fossa, no gurgling sound, and no tympanitis whatever. When the symptoms enumerated had continued for several days, a change for the better set in. That was on the seventh day of the illness. Even during the febrile period the temperature increased but to 102°, and on the eighth day to 100° ; the dryness of the throat left her; the pain in the shoulder gradually ceased, the perspiration became less profuse, the skin-eruption disappeared, and the throat and tongue regained their normal hue, though rather slowly. By the twelfth day all morbid symptoms had vanished, and the patient entered upon a rapid convalescence, though, considering the shortness of the malady and its character, she was emaciated to a high degree and remarkably feeble during the first week of her recovery. For nearly the whole of this week the tongue evinced some indication of its former morbid condition by its darker tint. When I visited the patient for the last time, at the end of the third week, she informed me that she knew almost nothing of what happened during the first four or five days of her illness, and that she only remembered that it had seemed to her as if she were in a strange room, lying upon the shelf of a closet instead of in the bed, and that she had tried to collect her thoughts, but that she had not succeeded, until she one day had a clear idea of herself and where she was. That must have been on the fifth or sixth day of her sickness, during an afebrile period.

I have mentioned this incident as indicating the serious nature of the complaint, for such aberrations of the mind happen only in the graver kinds of acute infectious diseases. With very little alteration, the above is the history of all the cases. Only in one instance, also that of a young girl, æt. 17, I discovered a small whitish patch on the left tonsil. The false membrane had about the size of a silver threecent piece, looked much whiter and was much thinner than a diphtheritic patch. It disappeared within thirty-six hours. The fever and perspiration at certain hours of the day, the skin-eruption, the rheumatic pains, the affection of one shoulder-joint, the vomiting, coated tongue, and sore throat, and the feeling of debility and lassitude, were present in all cases, varying but in degree. As the disease lasted in all the same length of time, we have in this self-limitation another proof of the infectious character of the disease. But that an exposure to cold and wet seems to exert at least a predisposing influence I cannot doubt from the history of the cases. Every patient ascribed the disease to catching cold, and dated its commencement from an occurrence of that kind. Lizzie D., though diphtheria had been in the house in which she lived for two weeks, and though she had been in frequent and prolonged contact with every victim of it during that time, had not contracted the malady until, on the day before it broke out on her,—the weather being cold, chilly, and somewhat damp, — she had been washing windows and walking over wet places with torn shoes, and been doing so for several hours, so that her stockings were completely soaked when she finished her work. A somewhat similar element existed in each case.

That peculiar eruptions frequently accompany diphtheria and sore throat has often been reported. But recently Dr. C. Boeck published two such cases.* In one, eleven days after the beginning of the sore throat, and while the morbid symptoms of it had not yet totally disappeared, a characteristic multiform erythema set in, and, in a second case, one month (!) after the commencement of a follicular angina, and while the debility and lassitude, which so frequently endure for a long time after this disease (!), still continued, rheumatic

* Vierteljahrsschrift f. Derm. und Syphilis, 1884, p. 481.

affections accompanied by *purpura rheumatica* complicated the original malady. Though debility and lassitude, at least in my opinion, very seldom last so long in simple sore throat as Dr. Boeck states, I agree with him in his explanation of the accompanying phenomena. He believes that the accidental symptoms and the inflammation of the throat stand in causal connection to each other, and the numerous nerve-fibres of the pharynx, intimately connected as they are with the sympathetic, seem to him of special importance in this respect.

Sore throat, though more of a chronic character, is met with in weakened conditions of the heart, as in fatty degeneration and dilatation of the organ (probably due here to venous stasis); syphilis may give rise to very severe forms of acute angina, and in rheumatism tonsillitis is not a rare complication, while in scarlatina it is the rule, in rubeola not the exception, and in morbilli but seldom completely absent. There are still other diseases, too numerous to mention, in which a sore throat is a common occurrence. There, further, is a difference between the catarrhal angina which develops from a catarrhal inflammation of the Schneiderian mucous membrane of the nose, travelling downwards, and the form where the inflammation has its acute beginning in the pharynx and usually stays there. This last variety is what I call the simple acute sore throat. An individual suffering from it, when young and vigorous, will often continue to attend to his daily affairs, no matter how annoying and painful the ailment to him; but in a case of infectious sore throat the person attacked by it is listless and gloomy; he does not care to perform any labor, and, besides, such a patient is too weak from the very onset of the disease to follow his usual occupation. He is forced to seek his bed; while in the case of simple angina the individual, if a young and vigorous man, can rarely be persuaded to stay in the room.

If it be true that the numerous nerve-fibre connections of the pharynx with the sympathetic occasion the rheumatic symptoms and the skin-eruptions, we probably have an explanation of the fact that especially women are attacked by the form of infectious sore throat which is complicated by the two phenomena mentioned. Had I seen but one or two cases of this kind in women, or had the picture of the malady not been so uniform in its course and the grouping of its symptoms as happened in my five cases, I might have considered the occurrence an accidental one, for, though the number of patients is but very small, it is peculiar that they all were women. A physician meeting with such a case for the first time will be greatly puzzled, and especially young practitioners, still under the influence of the description which their teacher gave them of typical cases of disease, will either change their diagnosis several times or confess their inability to arrive at a definite conclusion.

A far greater number of cases than mine will have to be observed before we can say that the infectious sore throat always affects women in the manner described, or that it attacks all persons, whether male or female, adults or children, in the same way. Of one fact I am convinced, that there are two kinds of what we commonly call acute sore throat, the simple sore throat never showing the rheumatic symptoms confined to the larger joints, the skin-eruption, the ups and downs of temperature, the profuse perspiration, and the fiery, glazed tongue, while the infectious angina has these complications, as a rule, in women, but never gives rise to abscess-formation. But, while I think I am the first to insist upon this distinction between the two varieties, I am well aware of the fact that, without having in mind the possibility of the existence of the other kind, many authors have recently expressed the view that acute angina is caused by the same poison as diphtheria and is but a milder form of it. To this opinion I am not prepared to subscribe; for why is it that we have so very mild forms of pharyngeal diphtheria that they are discovered only, as it were, by accident, where the patient himself is not aware of its existence, and where the inspection of the throat reveals a slight redness and a very insignificant patch of false membrane? Still, I admit appearances are suspicious, and I have myself attended a case of sore throat in a family where the second patient, taken sick a day or two later and sleeping in the same bed with the individual suffering from the angina, was attacked by diphtheria. From recent investigations of Cohnheim and others, we know that several causes (for instance, emboli and

thrombi) may give rise to the formation of a false membrane on the mucous membrane of the throat, even simple infiltration of the submucous tissue (probably by pressure on the vessels) leading to it. The inoculation, therefore, of the mucus from such a sore throat, and its being followed by the formation of a false membrane, would be no definite proof that both diseases—infectious angina and diphtheria—are caused by the same pathogenic element. It is to be hoped that bacteriology will determine the question.

It cannot be said that in those cases which I consider as instances of infectious angina, a diphtheritic patch would be discovered if carefully looked for. In two of my cases (that of Lizzie D. included) I made the same objection to my own reasoning, and instituted a rhinoscopic examination, notwithstanding the difficulty attending it under the circumstances. Such patients cannot open the mouth widely enough, but by using a hook somewhat like Voltolini's palate-hook* I obtained a sufficient view of the posterior nares, the septum, and of the entrance to the Eustachian tube, to enable me to say for certain that a false membrane was nowhere deposited.

I do not think that a coaffection of the kidneys ever appears in simple acute angina; but I confess that I have commenced only this year to examine the urine of such cases. I had but two in my private practice, and in consultation I have seen none, as a second physician is rarely called in in acute tonsillitis, except in such complicated cases as those of the infectious form, when the eruption easily confuses the physician. In these two cases I found no albumen; besides, in this disease the excretion of the urine is probably never interfered with, while in the infectious variety the suppression of urine for at least twenty-four hours seems to be common. A fact like the last, doubtless, at once draws our attention to the function of the kidneys. It may be that this complication, should it be so uniform an occurrence as happened in my cases, will form an important factor in the differential diagnosis of the two diseases, even should it be demonstrated that the infectious angina attacks men with the same symptoms and complications as women. I may here mention that two of my patients menstruated during their illness. Lizzie D. did so on the second or third day, and in the other case the menses also appeared on the third day. In these two the discharge came at the usual time, so that the disease does not seem to exert any influence upon the menses.

Regarding prognosis, I can only report that my patients recovered without any untoward symptom. In some convalescence progressed less rapidly and left the patient weak for a longer time, but in the third week they generally were once more able to resume their customary occupation.

With reference to treatment, I always administer an emetic in the beginning. As long as vomiting lasts and the tongue appears coated, I give as little nourishment as possible. All my patients were young and vigorous, so that, instead of stimulating, I had more than once the idea of bleeding the patient, and would have done so, on account of the active inflammation, had not the feeling of general debility which attends these cases restrained me. This period usually continues to the third day, when, the irritability of the stomach having ceased, I let them take fluid, but nutritious, food, returning to solid aliment as soon as the condition of the pharynx permits its being swallowed without injury to the inflamed parts. I further advise the patient to use the following gargle every ten or fifteen minutes:

℞ Acid. salicylic., ʒj;
Acid. carbolic., ♏xxiv;
Sodii borat., gr. lxx;
Glycerin., fʒj;
Aq. destillat., fʒxj. M.
Sig.—Use as gargle.

Internally I order a teaspoonful, in half a tumblerful of water, of this medicine:

℞ Quininæ hydrochlorat., gr. xxxvi;
Tinct. ferri chlorid., fʒj;
Acid. muriat. dilut., fʒij;
Tinct. cardamom. comp.,
Glycerin.,
Syrup. aurant. cortic, āā q. s. ad fʒiij.
M.

This is taken every three or four hours until the more moist appearance of the tongue and the general condition of the patient indicate amelioration of the symptoms, when the size and the frequency of the doses are rapidly diminished. As soon as the first indication of disturbance of the urinary function sets in, I prescribe

* Die Rhinoscopie und Pharyngoscopie.

a teaspoonful of infusum digitalis to be taken every four hours. When the secretion has been re-established, I still continue for one day longer the same dose; for another day the patient is directed to take it but three times daily, and then this medicine is stopped, having achieved its purpose. If the pain in the neck or in the shoulder be very severe, I have found the best result from this liniment:

℞ Chloral. hydrat., ℥j;
Camphoræ, ℥ss;
Ol. amygdal., f℥j. M.

Sig.—To be applied with a camel's-hair brush to the painful parts, the application to be renewed on return of pain.

Besides paying attention to the bowels and employing general measures, as regular feeding, cooling drinks, sponging of the body several times daily, etc., the above contains the whole treatment. For the sleeplessness commonly met with in the beginning I have ceased to prescribe, as experience has taught me that the patients feel better, regain sooner their natural sleep, and recover more quickly, when no hypnotic whatever is employed.

507 Franklin Street, Philadelphia, Pa.

THE LEGAL CONTROL OF MEDICAL PRACTICE BY A STATE EXAMINATION.

BY JOHN B. ROBERTS, M.D.,

Professor of Anatomy and Surgery in the Philadelphia Polyclinic.

Read before the Philadelphia Medical Jurisprudence Society, October 14, 1884.

IT is my intention this evening to briefly review the advantages that would accrue to the public and the medical profession by the enactment of a law placing the control of medical practice in the hands of a State Board of Examiners. As is known to many of you, a person who desires to practise medicine in Germany must pass a governmental examination. The students study in universities and take degrees, but such degrees do not confer the right to enter upon practice. The health and lives of the citizens of the empire are believed too valuable to be imperilled by the acts of ignorant physicians. Hence, although the universities themselves are under the supervision of the State, the candidate for practice must, in addition to his university examination for a degree, pass a governmental examination for license to follow professional work among the people of his vicinity. He is not a legally-qualified practitioner until this is accomplished.

The recklessness with which medical legislation has been neglected in this State will be apparent when I say that the medical schools are under no State or Federal supervision whatever, but have entire control of the time and character of studies required from the intending practitioner, examine him upon the same, and confer the medical degree, which is at once accepted by the authorities as evidence of sufficient knowledge and skill to entitle the possessor to practise medicine, surgery, and obstetrics in the community. Still further to encourage wholesale and unrestrained manufacture of physicians, the "doctor-manufactories" are, I believe, even exempt from taxation.

Until the year 1881 there existed in this commonwealth no law whatever regulating medical practice. At that time the law to provide for the registration of all practitioners of medicine and surgery was enacted by the General Assembly of Pennsylvania. It effected much good, and was a distinct step forward, though it has, among other minor defects, the weakness that the possession of a genuine diploma is taken as evidence of knowledge.

As long as the medical schools of the United States are dependent for prosperity upon the number of fees received from pupils, and as long as examinations by the faculties who receive these fees are the sole test of skill, a diploma, even from the highest-grade institution, carries with it little value as a diagnostic proof of professional learning. The old Latin proverb has it, "Caveat emptor" ("Let the buyer beware"). I say, "Caveat æger" ("Let the sick man beware"), if he believe that the fact of graduation from a renowned college confers intelligence and skill. The placard "No reasonable offer declined" usually tells the buyer that inferior quality of goods is to be expected. Would that many colleges had the honesty to display a similar escutcheon over their portals, reading, "No reasonable ignorance rejected!"

The step I advocate to-night is the creation of a Board of Medical Examiners, under State jurisdiction, who shall examine all persons desiring to enter upon practice in this State after January 1, 1886, without

regard to when, where, or how they obtained medical education. If such an examination by non-interested persons show the proper qualifications, the candidate is to be furnished with a certificate, and is then registered in the Prothonotary's office as heretofore. Let the medical schools teach, examine, and grant degrees as at present, but let no one practise in this State who has not been examined by those who have no interest in passing or rejecting him. In other words, merely substitute for the diploma the certificate of the State Examining Board as the requisite of registration.

The greatest advantage derived from such a law would be the protection of the public health from ignorant physicians. Bear in mind that I refer now not to Indian medicine-men, negro herb-doctors, and other charlatans, but to ignorant physicians, graduates of recognized and reputable schools of the United States and other countries,—such as are duly armed with beautifully-engraved diplomas signed by leaders of the profession, and therefore more dangerous to the community than a whole tribe of Indian "pow-wow-ers." These, indeed, assume the virtue of knowledge, though they have it not.

The United States government long ago adopted a similar plan of examining candidates for its army and navy medical services; so that at the present time its soldiers and sailors, even in distant territories and seas, have an average benefit of better-educated physicians than citizens of New York, Philadelphia, or Boston. An army or navy surgeon receives his education in any school, but he enters the Federal service only after an examination by a board who had nothing to do with teaching him, and who have no pecuniary interest in passing ignorant candidates.

A second advantage of the plan advocated is the improvement in registration that would take place. By the present law, persons who were in continuous practice for ten years prior to its enactment were allowed to register without diploma and without examination. Such persons, if any such still reside in the State unregistered, or if any new ones come into the State, would by the new law be required to show their qualifications for practice by examination. This would be a gain, as it would exclude a certain proportion of uneducated persons. Again, Section 4 of the Registration Law requires persons coming into this State with diplomas from other countries or States "to lay the same before the faculty of one of the medical colleges or universities of this commonwealth for inspection, and the faculty, being satisfied as to the qualifications of the applicant and the genuineness of the diploma, shall direct the dean of the faculty to endorse the same; after which such person shall be allowed to register." This imposes a considerable amount of work upon the medical schools, which, doubtless, would gladly be excused from this unpaid and uncongenial labor; for to reject the diploma or graduate of a neighboring institution lays the school open to unjust criticism. Moreover, the law does not state that the said colleges should be schools for undergraduates.

Some months ago, application was made to me, as Secretary of the Philadelphia Polyclinic and College for Graduates in Medicine, for certification of a man's qualifications for registration under this act. Undoubtedly post-graduate medical schools were not intended by the law, and I declined to act in the matter. Moreover, there are loopholes in the Registration Law by which punishment for practising illegally can be escaped. A notable case occurred six or seven months ago in Clearfield County, and is mentioned in an editorial published in the *Polyclinic* for March, 1884.

An exceedingly important result of the establishment of a State Examining Board in Pennsylvania would be the elevation of the standard of education in the medical colleges of the country. Many citizens and prospective citizens of the Keystone State study in the colleges of New York, Maryland, Ohio, Michigan, and other States. As soon as it is known that no one can practise in this wealthy commonwealth unless he passes the State examination, such persons will study in the highest-grade schools, and in those whose graduates show the smallest percentage of failures before the Pennsylvania Examining Board. Hence, if our schools are the best equipped and supply the best education, men will not pay their money to the teachers, boarding-house-keepers, and merchants of other States, but will attend our own schools, and thus increase the business prosperity of Pennsylvania. The

competition of low-grade colleges, whether in this or neighboring States, would not then tend to paralyze the efforts of institutions of high educational standard. There would be no longer a premium offered for quick graduation after two years' study and a five minutes' oral examination in each of seven branches.

Another indirect advantage would be this: that students could study in several institutions, and thus gain the benefit of hearing the foremost teachers of various schools, instead of being cognizant with the precepts of but one faculty. The former method of study is certainly the most elevating, as it broadens professional knowledge.

The division of labor resulting from examinations being held by a non-teaching board, having committees in different parts of the State, would make it possible to hold written and manipulative, as well as oral, examinations, and thus do better justice to candidates than is possible by an oral examination alone. Again, the examinations not being held all at one time of year would further accommodate intending practitioners and lessen the labor of the examiners. As it is now, the college faculties, with great inconvenience to themselves and often with injustice to the pupils, hurry through the examination of several hundred students in a few days. A gentleman now dead, who was for years a professor in a large medical school, once told me of a case where a man who failed to pass his examination was actually graduated because of a clerical error that occurred in the hurry of commencement time. Neither of us know how many people owed their deaths to that accidental physician. Bright men may have been neglected by similar errors made in hasty examinations. The State Board examination would be conducted leisurely, and, being partly written, would show by the records whether a man was unjustly rejected. He would also have the right to a public appeal from the report of the board, which now he has not. The college examination is, as it should be, under the present arrangement, the private business of a private corporation, and therefore sealed from public inspection.

Another advantage which deserves consideration is the power of revoking a man's license to practise which would be possible if a State Examination Board were instituted. His diploma cannot and could not be taken away, but his certificate of knowledge, character, etc., could be cancelled or withdrawn by the Board if he were convicted of criminal ignorance, malpractice or similar crime.

The last reason for advocating the law is cogent, but, to my mind, deserves little attention, because it is a selfish one, which should influence us much less than those previously discussed. Such an examination would weed out and keep out of the profession those persons who, though ignorant of medical science, accept professional duties and emoluments, and thus increase the difficulty of an educated physician's gaining a livelihood. There are, undoubtedly, too many physicians for the needs of the closely-settled districts. Fewer doctors and better ones would be a boon to most sections of the State. The State examination would effect both objects. The legal profession has, I believe, certain restrictions to indiscriminate admission to the bar. Why should not the medical profession have some similar protection?

Dr. Isaac Ashe speaks of districts in Scotland where sixpenny charges are made by physicians, and says he knows of an English town of fifty thousand inhabitants where one shilling charges are made for medical advice. ("Medical Politics," The Carmichael Prize Essay for 1873, page 33.) He quotes from the *Medical Press and Circular* of September 11, 1872, page 216, the following charges adopted by a practitioner of thirty years' experience: "Midwifery, two shillings and sixpence; advice, sixpence; consultations, one shilling." Is there a barrister in England or an attorney-at-law in Pennsylvania who accepts such insignificant fees for professional services? Yet the position of the medical profession in Pennsylvania is little better than that mentioned in England. The poor estimate put upon medical services is due to the overcrowded state of the profession and the inferior quality of much medical work, both of which conditions would steadily decrease after the initiation of a State examination.

That the medical profession desires the adoption of a State Examining Board may be assumed from the recent action of the Philadelphia County Medical Society. At a meeting of the present month, in which this and kindred educational topics were

discussed by college professors and practitioners, both general and special, the following resolutions were offered. After postponement for printing and circulation, they were adopted almost unanimously:

Resolved, That the Philadelphia County Medical Society believes that the status of the medical profession of this State will be elevated by the establishment of a non-teaching Board of Medical Examiners, whose certificate shall be the only one accepted by the prothonotary's office for physicians registering after January, 1886.

Resolved, That the other county societies of this State be requested to advocate the establishment of such a board at the next meeting of the State Society, and to discuss the matter prior to that meeting with the members of the General Assembly resident in their counties.

Resolved, That the Corresponding Secretary be directed to transmit a copy of these resolutions to the Secretary of each county society, with the request that immediate action be taken and reported to this Society.

Resolved, That a committee be appointed to draft a law creating a State Board of Examiners, for the examination of all persons for license to practise medicine, the said law to be presented at the next meeting of the Medical Society of Pennsylvania by the Philadelphia delegates to that meeting.

Having spoken of the advantageous action of a State Examining Board, I must hastily consider the objections that will be raised to its enactment.

It will be said that physicians living outside of this State, but near its border, are often called to attend patients in Pennsylvania. Very well; let them be examined by the Pennsylvania Board and register in the county of this State nearest their residences. Shall a physician of New Jersey, Maryland, Delaware, New York, or Ohio practise continuously in Pennsylvania without being subjected to the same examination as residents of this State? Certainly not. Those, however, who come into the State as consultants with duly licensed practitioners of this State should, of course, be excused from the State examination. So should dentists who do not practise medicine, whether residents or non-residents of the State. In the same manner midwives, who attend the very poor in cases of confinement, should be exempt from professional examination, though they undoubtedly should be registered and give some evidence of obstetric knowledge.

A physician changing his residence within the State would merely be required to register in his new locality, but would have to pass no second examination. Nor should those now legally registered and practising be required to pass the State examination.

It will be urged as an objection that there are physicians who desire to practise special systems of medicine, and that such a State examination would exclude these from practice. Not at all. Let the board examine all candidates on anatomy, physiology, pathology, hygiene, surgery, obstetrics, chemistry, and materia medica only, omitting theories of medical practice and therapeutics entirely from the schedule.

I have thus advocated, Mr. President and gentlemen, a measure which will, I believe, add to the wealth and prosperity of the State of Pennsylvania and elevate the profession of medicine, for whatever elevates the latter must increase the former. The wealth of a community is the health and lives of its citizens. Every useful life saved, every illness shortened, adds to the public treasury. The educated physician may do both, the ignorant physician does neither. I pray you to aid in cultivating the one and eradicating the other.

REPORT ON LARYNGOLOGY AND DISEASES OF THE NOSE.

BY CARL SEILER, M.D.

So much interest has been shown by the general practitioner in the success of the new treatment of hay-fever and rose-cold by the galvano-cautery, that a few words will not be unwelcome to the readers of the *Times*, although the subject is not a very novel one.

As is well known, hay-fever, as a disease very prevalent in America and England, has received a great deal of attention, and many papers and treatises have been written, in which almost exclusively the pollen-grains of this, that, or the other plant have been named as the cause of the trouble. A notable exception is found in the papers by Helmholtz and Salisbury, who ascribe the disease to vibrios and animalcules, and recommend solutions of quinine as a local application. The other authors, up to within a very few years ago, all recommended the removal of the patient during

the time of the attack to a locality which was free from the emanations of the particular plant affecting the patient. There are a few whose observations led them to believe that the hay-fever attacks were manifestations of a general nervous disorder, and recommended sea-air and nerve-tonics as the main elements in the treatment.

In 1882, Dr. W. Daly, of Pittsburg, published a record of some cases in which, after removal of nasal obstruction, the usual attack of hay-fever had not come on in the patients operated upon; and in 1883, Dr. J. O. Roe, of Rochester, read a very exhaustive paper on the causation and treatment of hay-fever before the New York State Medical Society, in which he demonstrated that the disease depended upon a peculiar sensitiveness of the mucous membrane of the nose, due in most cases to hypertrophic swelling of the cavernous tissue, but present in others without such evidences of nasal catarrh. Following up his theory, he employed the galvano-cautery knife for the destruction of this hypersensitive mucous membrane, and as a result gave the history of a number of cases cured by this method.

Since then, several other American and German laryngologists have published papers in which they substantiate Dr. Roe's observations as to the initial cause of the disorder, and add to the accumulating evidence of the effectiveness of his method of treatment.

There is, however, a slight difference of opinion as to the time when the application should be made, some claiming that a destruction of the irritated tissue during the attack is quite feasible and will cut short an attack, while most others hold the opinion that the galvano-cautery should be used either before or after the attack.

I have had ample opportunity to test this matter during the past season, and have found that the application of the galvano-cautery to the nasal mucous membrane after the attack had set in rather aggravated the symptoms, and in no way cut the attack short. On the other hand, I found that in those cases in which the treatment was begun before the onset of the disease, the attack was either prevented altogether, or, in a few instances, was greatly modified as to severity of symptoms and duration.

In one instance a single application, made two weeks before the time at which the attack was expected, in a case of twenty years' standing, proved sufficient to prevent any symptom of the disease from making its appearance. As I have frequently reiterated elsewhere, the application is not at all painful if properly made.

Two important subjects were discussed, among others, at the meetings of the Section for Laryngology at the International Medical Congress in Copenhagen,—viz., the use of chromic acid as a caustic in nasal diseases, and the use of inhalations in the treatment of diseases of the upper air-passages.

Dr. Hering, who opened the discussion, said that chromic acid was destined, in his opinion, to set aside galvano-cautery and other caustics, and could be used with great advantage for the removal of hypertrophies and pedicles of polypi. His method of application is to melt a small crystal of the acid to the end of a probe, and to touch with it the tissue to be destroyed, and then wash out the nose with a weak solution of bicarbonate of soda. He claims that the chromic-acid application is less painful and the wound made heals more rapidly than is the case with the galvano-cautery. Most of the gentlemen taking part in the discussion said that they had used chromic acid in the manner described or in concentrated solution (Boeker, of Berlin), but had found that the galvano-cautery was not in danger of being set aside for this reagent. The application of chromic acid in the form of crystals for the destruction of tissue in the upper air-passages is by no means a new departure, but it was used many years ago, and fell into disuse with the advent of the galvano-cautery. Lately, however, as it so often happens in medicine, that a forgotten remedy is again brought to light, this method of cauterization has received renewed attention by laryngologists, and Dr. W. C. Jarvis reported a very interesting case of large papillomatous growth of the larynx removed by repeated applications of chromic acid crystals at the meeting of the American Laryngological Association last spring. At the same meeting, Dr. Donaldson, of Baltimore, read a paper on the removal of nasal polypi by chromic acid. There are undoubtedly cases in which this caustic is preferable to the galvano-cautery, as in

Dr. Jarvis's case, but in most instances the galvano-cautery is preferable, not only on account of the greater facility of its application, but also on account of the freedom from all further destructive action after the knife has been removed.

Dr. Schnitzler, of Vienna, opened the discussion on the inhalation treatment, and expressed it as his opinion that inhalations were particularly useful in diseases of the upper air-passages, but were also valuable where the disease was located in the bronchial tubes and in the lung-tissue, where topical applications could not be made.

In the discussion, Gottstein, of Berlin, declared that inhalation was a method of treatment at once unscientific and often harmful, because the application could not be localized, and because frequently the convergent inhalation was prescribed in cases demanding early topical applications, and thus much valuable time was lost. Schaeffer, of Bremen, expressed the opinion that laryngoscopy would be more universally practised among general practitioners if the convergent inhalation method of medication did not seem to make the use of the laryngeal mirror superfluous.

There is a great deal of truth in the remarks of Gottstein and Schaeffer, for it is a deplorable fact that but too often inhalations of atomized liquids are ordered by the general practitioner without his having made a careful examination of the larynx, and without any reference to the condition of the parts. Nitrate of silver and astringent solutions are thus used indiscriminately. Gottstein, however, goes too far in declaring inhalations irrational, for, as Dr. Beschorner, of Dresden, in the same discussion, remarks, there are cases in which inhalations cannot well be dispensed with,—as, for instance, in diphtheria and in the sore throats of children; and at the same time the forcible inhalation treatment is found a most valuable addition in the treatment of chronic phthisis.

A short time ago, Dr. Bosworth, of New York, read a very interesting and exhaustive paper on the "Three Tonsils," at a meeting of the New York Academy of Medicine, in which he discusses fully the pathology of "quinsy" and the advisability of excision of hypertrophied tonsils. He entertains the view that in quinsy the tissue of the tonsil is not directly involved in the inflammatory process, but that the disease is, in reality, an acute cellulitis of the areolar tissue of the fauces, which later involves the tonsils secondarily. The cause he believes to be rheumatic habit in sixty per cent. of all cases, and the treatment consisting of salicylate of soda internally, based on this theory, was most generally successful in preventing suppuration and hastening resolution. As a local application he used bicarbonate of sodium, with gratifying results. In regard to hypertrophied tonsils, he advocated ablation of the glands, and said that the prevalent idea held by many practitioners, that cutting off a small portion of the tonsil would cause a shrinking of the rest, was erroneous. Hemorrhage was, as a rule, insignificant, particularly in children. The "third" tonsil, he said, was the collection of glands situated on the vault of the pharynx, variously designated by different authors as "adenoid tissue," "pharyngeal tonsil," etc. This collection of glands differs in nothing from the faucial tonsils, and is subject to the same pathological changes,—viz., inflammation and hypertrophy,—which should be treated in the same manner as when occurring in the faucial tonsils.

These views regarding the tonsils, and particularly as to the cause of tonsillitis, have been advanced of late by laryngologists and clinicians, and are gradually gaining ground; yet, at the same time, the percentage of those cases of quinsy caused by a rheumatic tendency seems to me somewhat too high, for in my individual experience I have met with but a few, and found the salicylate of soda in the other cases of no value whatever. In the same way did the bicarbonate of sodium, locally applied, give but very doubtful results in my hands.

Ergot in the Treatment of Constipation.—Dr. Granzio reports two cases of constipation following the abuse of purgatives relieved by ergot. Three doses of ten grains each were given at intervals of two hours, and were followed by a copious evacuation. A second stool occurred spontaneously the next day, and, after the administration of ergot in smaller doses for a few days, a definite cure was obtained. The constipation was due to atony of the muscular wall of the intestines. (*Allgemeine medicinische Central-Zeitung*, May 24, 1884).—*Practitioner.*

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

CLINICAL REMARKS ON POST-TYPHOID ELEVATION OF TEMPERATURE.

BY J. M. DA COSTA, M.D.

GENTLEMEN,—I wish to call your attention to certain cases of post-typhoid elevation of temperature,—cases which cannot strictly be classed among those of relapse or of recrudescence of typhoid fever. It has happened to me to see, both in this hospital and in private practice, a number of patients who, after passing through the course of the disease, still retained a fever-temperature, or if, as is much more usual, the temperature had for a time resumed its normal status, it went up again, without a redevelopment of diarrhœa, the appearance of rose-spots, or the return of cerebral symptoms. I have seen it shoot up as high even as 105°, and almost as quickly go down again to the normal, or even below. It was only yesterday that I met a physician in large practice in this city in a case of a boy convalescent from typhoid fever, in which the temperature on two occasions went up suddenly to 105°, without there being any signs of relapse of the disease, and on both occasions there were no other manifestations of systemic disturbance, and the temperature soon went back again to normal.

In the case I show you this morning something of the kind happened. His history is a long one, of which I need only give you the outline. His name is Thomas T., 20 years of age, born in Ireland. He was admitted September 22, 1884, after five days' sickness with typhoid fever. He has been here for nearly three months. The temperature, with the usual fluctuations, returned to the normal at the end of four weeks; during this period he went through the regular course of a typhoid fever of rather more than usual severity. After he had passed the height of the disease, his recovery was delayed by an attack of milk-leg. When this had subsided and his temperature had become normal and had so continued for several days, he had a sudden rise of temperature to 104° one afternoon (November 3), but there were no other symptoms of disorder, and on the next day the temperature was 100°, and afterwards gradually subsided to normal. I find that the temperature again rose on the 20th of November to 101½°; subsequently it remained steadily high for nearly a week.

There is a class of cases, of which I have seen a number in former years of service in this hospital, in which there is a sustained fever-temperature after all the other signs of the disease have passed away and the patient is convalescent. In this class of patients I have seen the temperature fall from 100° to normal as soon as they were allowed to get out of bed. The temperature would apparently remain elevated indefinitely, without any other sign of disease, as long as they were kept in bed. This has taught me that in some cases, if you want to get them well, you must get them out of bed: too much coddling does harm. The sustained abnormal temperature makes the physician, nurse, and patient afraid, although all the other appearances are favorable. When the patient is allowed to sit up, gradually extending the time, the temperature falls.

There is another class to which I wish to direct your attention. Of course it is understood that elevation of temperature often occurs from indiscretion in diet: these instances I need not refer to further. I merely mention them to complete the series. In this man the first elevation I referred to was caused by reading a book, and that in the boy had a similar cause. The boy was of very impressionable nature, and, when a schoolmate called upon him and insisted upon seeing him after his attack of typhoid fever, he became very much excited after his friend had gone away, and cried for some time. That evening his temperature went up to 105°. Mental emotion, then, may be a cause of high temperature during convalescence from typhoid fever.

This does not, however, completely cover the case before you. I took the patient out of bed, forbade any excitement or mental effort, but the temperature continued high, although he had no diarrhœa or other symptom of disease. Examining the case repeatedly, I could find nothing but constipation that was amiss. Upon looking carefully for a cause why the temperature remained elevated, it occurred to me that it might be due to constipation; the fever-temperature being caused by irritation of hard masses

of retained fæcal matter in the intestine. I ordered this man a daily enema and one drop of the fluid extract of belladonna three times a day. This I had found in previous cases effective in correcting a tendency to constipation after typhoid, where irritating purgatives would be dangerous. Now, here the effect was very soon apparent. I have to report that the temperature fell to normal as soon as the intestines were freely evacuated, and has remained so. He now has a daily movement of the bowels, feels well, though still weak: his temperature is $98\frac{1}{2}°$. He is no longer confined to his bed.

TRANSLATIONS.

Treatment of Diphtheria. — The *Centralblatt für die Gesammte Therapie* mentions three varieties of treatment which have recently been brought forward. A solution of corrosive sublimate (one to ten thousand) is hourly applied to the throat, each time using a new feather (absorbent cotton upon a stick would probably answer the purpose very well), by Dr. Rudolph Canstatt, Uruguay. Dr. Moly reports excellent results from the following: on the first day every fifteen minutes, on the second day every hour, finely-pulverized camphor is applied by a brush, or with the fingers; at the end of forty-eight hours even the worst cases show striking improvement. He lost, out of one hundred and forty-three, only two cases, one of which was for too short a time under treatment, the other was refractory. Dr. F. Kuchenmeister recommends a treatment which he has used for twenty years. He dilutes Volquardt's mixture (℞ Sodii nitrat., Sodii carbonat., Aquæ, āā 2 G.) with water 100 and syrup 20. The sodium salts appear to act upon the blood, and especially its protein albumen, and also in such a manner as to reduce the fever. He also applies a sublimate solution locally several times daily, and uses lime-water (diluted three-fourths with water) as a gargle. The union of the lime-water with the sublimate is considered a favorable one, because the diphtheritic membrane is first dissolved, and the sublimate solution attacks the germs and destroys their activity.— *Deutsche Amerikan. Apotheker Zeitung.*

Treatment of Auricular Vertigo by Surgical Operation.—Weber Liel recommended, and has practised for a long time already, the section of the tensor tympani muscle as an extremely efficient means of treatment for certain attacks of vertigo due to ear-disorder. The following case (*Monatsschrift für Ohrenheilkunde*, 1883, No. 11) demonstrates very conclusively the value of this treatment in proper cases. A man 44 years of age, a clerk, suffered from intense degree of vertigo, weakness of hearing, and tinnitus, supposed to be the result of a blow on the head received in a fall while drunk. He could not walk even a few steps without staggering. Examination showed that the only appreciable lesions were in the auditory canal and the tympanic membrane of the right ear. Nothing was present to indicate that a cerebral cause for the vertigo existed. Rarefaction of the air diminished the tinnitus and the vertigo. Weber Liel then performed tenotomy by section of the anterior portion of the tympanic membrane. The success was immediate and striking. The patient was able to execute all the movements of the head rapidly and in all directions, turn in a circle, etc., without experiencing the slightest disagreeable sensation. Moreover, the noises in his ear, which had been so annoying as to keep him awake at night, became so much softer that they were quite bearable; and later it was found that his hearing had notably improved. The operation was performed in 1879, and the vertigo has never returned since that time. —*Annales de l' Oreille, du Larynx et des Organes connexes.*

A Clinical Test of Lead-Poisoning. —Dr. Du Moulin recently presented before the Académie Royale de Médecine de Belgique (*Revue Médicale*) a young man affected with saturnism, whose skin, when painted with monosulphide of sodium or sulphide of ammonium, gave a well-marked plumbic reaction. This test for the presence of lead in the system by testing the skin with an alkaline sulphide he referred to as a new and curious pathognomonic symptom which often appears earlier than the blue line on the gums, and as more characteristic and demonstrative than the latter. [This is in accordance with the observation of Dr. Pereira, that lead is eliminated by the skin.]

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, DECEMBER 27, 1884.

EDITORIAL.

THE PROPOSED ACT OF THE LEGISLATURE CREATING A STATE BOARD OF MEDICAL EXAMINERS AND LICENSERS.

A BILL has been prepared for presentation before the Legislature of Pennsylvania during the present winter, having for its object the establishment of a permanent commission to be known as the State Board of Medical Examiners and Licensers, which shall have the power to pass upon the qualifications of all physicians seeking to practise medicine or surgery in the State of Pennsylvania after the 1st of September, 1886. As the bill has been framed with evident care by a Committee of Conference consisting of members of the Philadelphia Medical Jurisprudence Society, members of the Philadelphia County Medical Society and Pennsylvania State Medical Society, as well as from the Homœopathic State Medical Society of Pennsylvania, we will review its main points of interest.

There are several very good features in the proposed bill. In the first place, as to the constitution of the Board, it has been wisely, we think, provided that the Governor shall be restricted in his choice of the nine members to a list presented by the two chartered State medical societies, which shall nominate three candidates for each vacancy,—with the provision, however, that the proportion between the regular and homœopathic members shall be as seven to two. Five members, of whom one at least shall represent the Homœopathic Society, are to constitute a quorum. The only officer of the Board to be paid out of the State Treasury is the Secretary and Treasurer, who shall receive a salary (the amount to be fixed by the Board), and who shall give bonds for the faithful performance of his or her duties. The remuneration of the several members of the Board is to be paid from the fees received for examination, provided that any excess over and above seven hundred dollars each per annum, after deducting necessary expenses, shall be paid into the public treasury. The Board shall hold two stated meetings each year,—one at Philadelphia on the second Tuesday in May, and one in Pittsburg on the second Tuesday in November,—and, in addition, as many special meetings as it may deem proper.

The examinations must be in writing, and the papers must be preserved for five years, during which time they will remain open for inspection at the office of the said Board, which shall be in Philadelphia. The examinations shall be in anatomy, physiology, histology, general chemistry, pathology, therapeutics, principles and practice of medicine, surgery, and obstetrics. The fee for examination is fixed at twenty dollars; a second examination, in case of failure to pass the first, will be held without additional payment of a fee. All candidates are required to pass the same examinations, except upon principles and practice of medicine, upon which subject two sets of papers shall be prepared by the regular and homœopathic representatives upon the Board, the candidate to elect which he wishes to be examined upon. As each candidate is to be known only by a confidential number, it is believed that this will prevent any partiality, as the papers will be judged strictly on their merits. The records of the Board are required to be kept open for public reference, and a list of those candidates who have received licenses shall be published each year.

An important provision is that conferring the power to revoke a license: upon charges of unprofessional conduct being

brought and sustained by investigation, the Board of Licensers shall bring the case to the attention of the District Attorney of the county in which he or she may have practised, in order that the offender may be summoned to appear and show cause why his license should not be revoked. The court shall have the power to direct that such license shall be stricken from the list recorded in the office of the Prothonotary of the Court of Common Pleas for the county in which the said accused shall reside. An adequate penalty is provided for violations of this act. It is provided that any person violating the provisions of this act shall be guilty of a misdemeanor, and, if convicted, shall pay a fine of not less than fifty nor more than five hundred dollars for each offence. The clause in the Registration Act of June 8, 1881, referring to the endorsement of foreign diplomas by local medical faculties, is repealed and annulled.

This act, if it become a law, will only affect those who enter upon the practice of medicine in this State after the 1st of September, 1886.

Some considerations suggested by this bill are embodied in a leading article in another column.

THE NEED OF LEGAL CONTROL OVER MEDICAL PRACTICE.

THE series of papers which have appeared among our original contributions recently, notably those by Dr. Gihon, Dr. Jackson, Dr. Keyser, and Dr. Roberts, has presented the necessity of legal control over the practice of medicine in such a strong light that we had not intended to refer to it further; but we cannot forbear quoting a case which was before our courts last week, which, taken as a fact, demonstrates the correctness of the proposition more conclusively than pages of argument. A man in the northern part of the city died while under the care of a "professor" who makes and sells his own medicine. The widow called upon the professor for a death-certificate, when, she says, she learned for the first time that he was not a doctor and not entitled to sign a certificate. He was afterwards brought up to answer to a charge of malpractice, when he explained that he was formerly a real estate agent, had no medical education, and did not know that the law could prevent him from making and selling a medicine which he knew was good because it had cured him. The title of Professor he had adopted because he professed to make and sell medicine; he also had been in the habit of attending the sick when requested to do so. He was held by the magistrate to answer at court.

If anything were needed to discover to the world the contemptuous estimate which is put upon the responsibilities of medical practice by some in this community, and which derives at least tacit support from laws not sufficiently stringent, or inadequately executed, to prevent such an abuse, we think that cases like this would do it. For the protection of the reputation of Philadelphia as a medical centre something should be done to elevate the practice of medicine. Might not colleges of this city establish a board of censors, or regents, who could strive to have proper laws framed to protect the community from impostors, and be charged with the duty of seeing them enforced and offenders prosecuted in the courts? The New York County Medical Society has spent thousands of dollars in seeking out and punishing offenders against the medical laws. Will our County Medical Society be sufficiently public-spirited to spend some of its accumulated saving for the same good object?

WE regret to notice the death of Dr. James G. Thomas, an eminent physician of Savannah, while in attendance at the meeting of the General Committee of Organization of the Ninth International Congress at Washington.

LEADING ARTICLES.

ARE LAWS REGULATING THE PRACTICE OF MEDICINE CONSTITUTIONAL?

IT may be asserted, in objection to medical legislation, that, as the public in a free country has a natural right to choose its own medical advisers, an equal right exists on the part of medical men to practise medicine free from any restraint by law. Moreover, it has been claimed that laws restricting the practice of medicine really confer a franchise upon a certain class of men, thereby constituting class legislation, which is opposed to the spirit and letter of the Constitution of the State of Pennsylvania. It may also be urged that a law requiring a special examination and license before an applicant can be admitted to register as a physician and enjoy all the rights and privileges thereto pertaining is in itself inoperative and unconstitutional, at least so far as the college graduate is concerned, because the graduate in medicine has those rights and privileges secured to him by his diploma given under the seal of an institution acting under the authority of a charter by which it is fully empowered to confer such rights and privileges upon its approved students, and that the utmost that the State can do is to require a registration of the diploma and the payment of a fee. Finally, since the State accepts the diploma, if genuine, as an evidence of professional competency to practise medicine, as citizens of one State have all the rights and privileges of citizens of another State, it follows that the diplomas of schools in other States of the Union likewise confer the right to practise in Pennsylvania.

Without going into a general consideration of the increasing necessity of State supervision over those individuals entering upon the practice of medicine, we will merely state that this necessity will grow more pressing in proportion with the vigor with which medical laws are framed and enforced in surrounding States, thereby driving a horde of ignorant and unscrupulous pretenders to medical knowledge over our borders, to teach our people, by painful experience, the results of free trade in medicine. Unless some judicious legislation prevent, Pennsylvania seems doomed to become the Paradise of Quacks. Legislation, however, will be worse than useless unless judiciously framed and capable of being executed in the same spirit. That medical legislation can accomplish much good, if not all that the friends of reform desire in this State, may be considered as having been fully demonstrated by the labors of the State Boards of Health of West Virginia and of Illinois, the efficiency of which is universally acknowledged.

In reply to the objection mentioned at the beginning of this article, it is sufficient to say that the States do not recognize the right to practise medicine as a natural right, but always as one conferred upon the individual, a statutory right. This is proved by the fact that, in every State in which medical laws have been adopted, the right to practise medicine has been treated as one which has been conferred by the Legislature, and therefore may be controlled by statute providing for licensing to practise those who are found to be competent within its geographical limits, beyond which its authority does not extend. In fact, all who enjoy the right to practise medicine derive their authority to do so from the State, which may adopt a statutory provision requiring them to register, and it may also forbid their practising without a license.

The claim that such legislation restricting the practice of medicine to the hands of those who have given satisfactory proofs of their fitness is of the nature of class legislation, is so obviously untrue as scarcely to admit of discussion. The practice of medicine is not thereby confined to any particular class in the community, but remains free to individuals of all classes who qualify themselves for its duties by due preparation. It confers no exclusive prerogatives, and excludes only incompetency and ignorance, leaving the way open to all to attain the standard of qualification.

The third objection, however, demands a little more consideration. If there were no institutions in Pennsylvania possessing chartered rights to grant medical degrees upon persons possessing the legal qualifications to practise, the question would be a much simpler one to decide. If only physicians from other States were to ask for registration, the condition of affairs would be far different. For, as the power of a State to confer statutory rights and privileges is restricted to its own geographical limits, it follows that when a physician

emigrates from a State he leaves behind him such rights and privileges, and must submit to the regulations of the State in which he settles before he can enter upon the practice of medicine within its borders. With regard to those physicians who have diplomas from institutions outside of Pennsylvania, it is clear that the Legislature has the right to require them to obtain a license and give evidence of their fitness before being admitted to registration. But that such a course can be pursued in dealing with graduates of our own medical colleges is another question. An eminent jurist* has recently given a decided expression of opinion upon this subject, as follows: "The State may doubtless create a board of health or a similar body, and require every physician to register his license with the board, or in the office of the county clerk or other appropriate place. But his right to practise will not depend upon his registration, as the right has been already vested and assured by the diploma and license of the college. And, should the State also vest this board of health with the right and even duty of examining and licensing applicants, it could not apply to those who held a license from the incorporated colleges. Nor could it militate against or invalidate in any way the right of the colleges to issue valid diplomas and licenses, before or after; for not even can the State by its legislation divest or impair a vested right which the colleges already had."

If Judge McGary is right, then, if we wish to have a State Board of Examiners and Licensers, the law must be framed so as to exempt the graduates of Pennsylvania schools from examination for license. Possibly the incorporated colleges might be persuaded to establish a conjoint examination-board (thus relieving them of the task of examining their students) and grant their diplomas and licenses only to those who are approved by the Board. As several members of the faculties have been much interested in framing the bill above referred to, it is hoped that the co-operation of the medical colleges may be secured in the great work of medical reform, in which the colleges, as well as the profession throughout the State, are so deeply interested. The question whether the particular proposed law to establish a State Board of Examiners and Licensers is constitutional or not, is one that deserves and will receive serious consideration. Of the general right of the State to make such laws there can be no reasonable doubt.

* Judge McGary, of Washington, in an article entitled, "Are Medical Laws Constitutional?" in "Health and Home" for September 15.

NOTES FROM SPECIAL CORRESPONDENTS.

LOUISVILLE.

ENDEMIC OF TYPHOID FEVER.

MR. EDITOR,—About the middle of August last, cases of typhoid fever began to appear here and there throughout the western part of this city. The endemic reached its maximum about the 20th of October, and since then has been on the decline, though not rapidly. The number of cases that have occurred is not accurately known, but the best estimates place it at three hundred to three hundred and fifty. The mortality has been about twelve per cent. At a recent meeting of the Louisville Medical Society the cause of the disease, with particular reference to this city, was made the subject for discussion.

Dr. J. M. Clemens, as leader of the discussion, read a paper in which he said in substance, "It is known to you all, gentlemen, that the epidemic of typhoid fever which has been prevailing for the past few months in our midst is of such proportions as to challenge the very best consideration of the subject by our profession.

"In my own practice there have occurred, since the middle of July, sixty-three cases: judging from the stand-point of my own experience with the disease, I should think there had been fully three hundred cases occurring in this city up to the present time. The period of greatest activity was about the middle of August, though isolated cases have been occurring for several months. The type has been generally mild, although all grades have been represented, from the mild or walking cases to the severest. The clinical features have not differed from what is already known and recognized as common.

"As to the factors concerned in the causation of this outbreak, the opinions which I have previously held and repeatedly expressed have been strengthened by the conditions and surroundings found to exist in connection with the cases I have seen. I accept the germ-theory of this and other kindred diseases. I believe that every febrile disease which runs a definite course, which is marked by characteristic features and stages,

is due to a specific organism. I hold this as especially true of contagious and infectious diseases, as I believe it is held in common by a great majority of the best medical minds at the present time, though there is still a very respectable minority that does not concede it.

"The theory of micro-organisms, in my estimation, furnishes the only basis upon which the origin and known factors of the disease can be explained. Although cases arise that are not clearly traceable to a previous one, yet instances are so numerous where the connection has been traced, even through a mysterious chain of circumstances, to a previous case, that the weight of authority is now in favor of that hypothesis. There are strong reasons for believing that the decomposition of fæcal matter develops, increases, or intensifies what might otherwise exist as harmless organisms. These, according to M. Pasteur, once introduced into the human body, reproduce themselves indefinitely and are largely eliminated by the intestinal discharges. The investigations of Klebs, of Prague, enable him to bear strong testimony in favor of this theory. He believes he has discovered the organism of the disease: he writes that he has been able to find at the necropsy of twenty-four cases microbes in the various organs which do not exist in cases of death from other causes. In the light of this theory, the most rational explanation of the outbreak in this city is afforded.

"I have but to call the attention of the Society to the fact that, at the time when the site of the city was chosen, the whole of this district in which the disease has to the largest extent manifested itself was a marsh, and that at the present time many ponds still remain. The river, which in previous years flowed in the general direction which it still maintains,—viz., from northwest to southeast,—at the present sweeps around the city in a magnificent curve to again assume that general direction. If I am correctly informed, a well may be sunk at any point in this city to the common depth and water found; that depth varies from twenty-five to sixty feet. The underlying geological formation consists of strata as follows: earth, boulders, gravel, sand, and clay, followed again by boulders, gravel, sand, etc. The water-stratum in this boulder-bed and that of the gravel must have a very free circulation. Now, it is the custom in this city to sink privy-vaults into the earth, and a vault sunk short of the boulder-bed, in order that the fluid contents may drain away, is considered a very poor makeshift indeed. Upon an average, it may be said that to every public well for drinking-water in this city there are forty vaults reaching down to the boulder-bed to contaminate it, and many of these wells, in addition, are befouled by surface-seapage, the walls serving as a kind of conduit, carrying down filth on the outside, to be pumped up from the inside.

It is a fact that, of the sixty-three cases I have had, all the subjects, except one, habitually drank this pump-water, and that one exceptional case drank it occasionally. Of my patrons in this typhoid-fever district who use the hydrant-water, but one has had the disease. Is not this chain of circumstances, to say the least, suggestive? I answer, bearing in mind the formation of the vaults as given, and the unusual water-pressure to which the ground-water has been subjected during our floods of last and the preceding spring, that such a theory bears something more than the stamp of plausibility."

In discussing this paper, Dr. William Bailey said he was inclined to think, from the specific character of the symptoms and the well-defined clinical history of typhoid fever, that it is due to a specific cause. What this is—whether a micro-organism or not—he was waiting to hear from those prepared to investigate questions of that kind. When the proof comes, he will be ready to accept it. He did not think that causal relations had been established as yet between these forms of bacteria and the diseases in connection with which they are found, and at present he had not fully accepted the germ-theory of disease. He did not think himself qualified to get at the facts as to whether micro-organisms are causal or concomitant; whether they originate the disease, or whether they come as an after-clap; whether they are scavengers in the wake of the disease, or whether they act first to produce it. He was somewhat heretical concerning the contagiousness of typhoid fever, and even was scarcely willing to believe that one case of typhoid fever is dependent upon another for its origin. The first case of smallpox must have originated *de novo;* but at the present time he believed that no one would expect a case of smallpox to arise in that way. Typhoid fever, however, he was inclined to think, is due to a local cause, whether atmospheric or not he did not know; yet local conditions do develop the specific poison, whatever this cause may be. Whenever the conditions are present it is developed, no matter where, and all who are susceptible to the cause coming within its influence suffer from its effects more or less. There are so many cases of endemics that seemed so clearly traceable to other causes than contagion that it renders all doubtful.

He recalled a case where the disease broke out in a school, but, strange to say, it occurred only among the occupants of one side of the house. When an inspection of the local sanitary conditions was made, it was found there was a break in the pipe used for drainage for that part of the building.

He had no hesitation in saying there is no possibility of communicating the disease by direct contact from the sick to the well. If there is any contagion at all, it is due to what

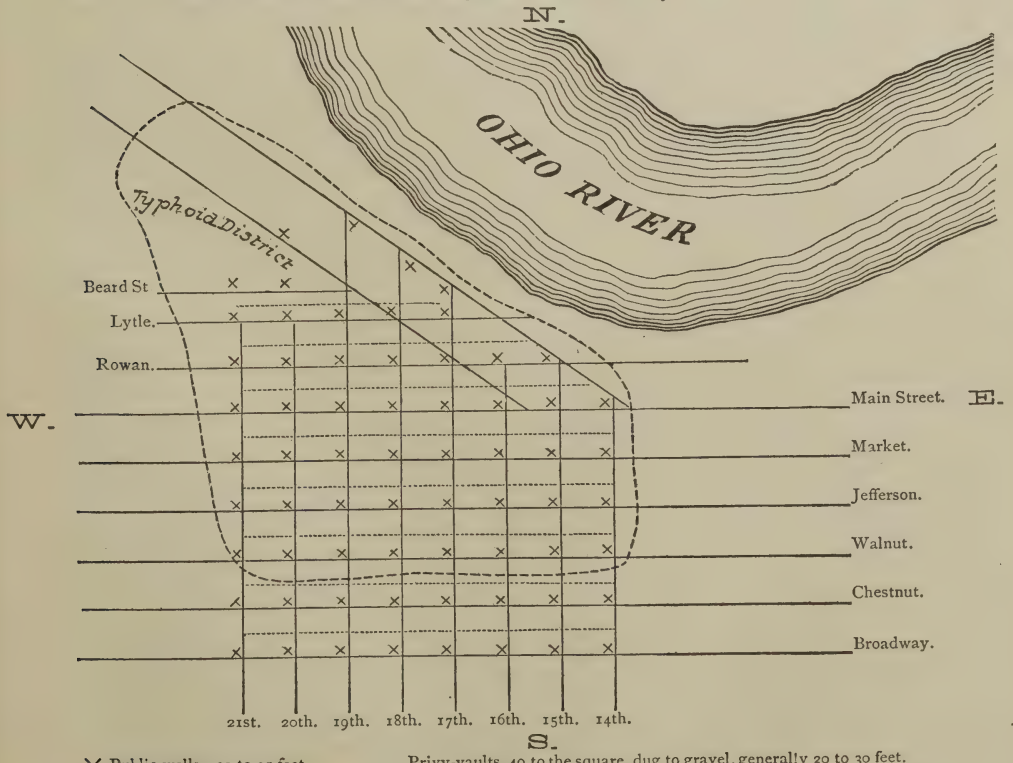
we recognize as miasmatic contagion, not directly from the sick to the well.

In concluding, he called attention to a paper read at the American Public Health Association recently held in St. Louis, by a distinguished sanitarian, Dr. Henry Baker, Secretary of the State Board of Health of Michigan, in which he took the position that typhoid fever was due to the lowering of the subsoil water; that typhoid fever is more prevalent in hot and dry falls, when the water sinks lowest in wells, and when poisons present in it must be more than usually condensed. This paper attracted a great deal of attention before this body of sanitarians.

The paper was discussed by Drs. Preston B. Scott, F. C. Wilson, J. Brandeis, Turner Anderson, and William Bailey, the speakers generally agreeing with the main points of the paper, although not considering the existence of a typhoid-fever germ as sufficiently established.

In conclusion, Dr. Clemens said he wished to dispossess the minds of many who have participated in this discussion that he had claimed that all these cases were due to the pump-water: other conditions and causes have long been recognized as productive of the disease. But, on the other hand, that many of them have received their infection from this source he did not doubt. The facts that have been elicited do not militate against the theory that these public wells are contaminated. He had simply brought forward these facts as such as to warrant him in the conclusion that the contamination of the water-supply had been mostly to blame for this epidemic. If this germ-theory be true, a gradual increase of the disease would be a reasonable deduction: that, as has appeared in the discussion, has occurred since the year 1880. That fact would also sustain the theory that the privy-vaults and their contents have acted as receptacles for the poison, in which to breed and intensify till a favorable condition for its development arises. Neither does it militate against this theory that cases have occurred in families that habitually use the hydrant-water, because in most families are children that go to school and are in the streets much of the time, and they no doubt, when thirsty, drink the water so kindly and conveniently provided for them on every corner.

At the conclusion of the discussion it was decided to continue the consideration of this subject at the succeeding meeting of the Society, following which the subject of the treatment of typhoid fever will be introduced in a paper by Dr. Turner Anderson. The following subjoined sketch of the condition of the city in the infected district may offer additional suggestions to those unacquainted with the city.



There seems to be a conflict of authority among the public health authorities. Yesterday, at a meeting of the City Board of Health, a communication from the Secretary of the State Board of Health, asking for a report of the precautions, if any have been instituted, against a possible outbreak of cholera within the year, was tabled, on the motion of the mayor, for the reason that the municipal Board of Health is an organization which is entirely independent of the State Board. This illustrates pretty well the status of the feeling of the City Board towards the State organization. The motley crew designated the City Board, when the subject of typhoid fever first began to attract public notice by its prevalence in this city, at first denied its existence to the extent reported, finally admitted its prevalence to the amount of three or four hundred cases, and then in the daily prints excused its wanton ignorance and neglect on the ground that it had no power to do anything, and that the people expect too much from the City Health Officer. The truth is, the people expect nothing from the City Health Officer, pay him two thousand dollars per annum for doing it, and—have their expectations fully realized.

The Secretary of the State Board of Health entered zealously into the work of investigating as far as possible the causes of the outbreak and the conditions probably perpetuating it. A report of his work will soon be before the profession. When this work was begun, the co-operation of the City Health Officer was solicited. The only response to this invitation so far made public was an announcement by the City Health Officer at one of the *séances* of the Board of Health that he and the small remainder of honorable members had never been *officially* requested to participate in this investigation!

COLLEGES AND HOSPITALS.

The medical college controversy between the representatives of the Louisville Medical College and the University of Louisville, consisting of Dr. Galt on the one side and Dr. Yandell on the other, appears to have had the effect of reducing the usual number of students in attendance at both institutions. The probabilities are that many of the charges brought against the Louisville Medical College by Dr. Yandell are true; on the other hand, Dr. Galt is doubtless a man of equal veracity, and no doubt many of the charges brought by him against the University are true. Each seemed to establish the charges he brought; whence very naturally follows the conclusion that no doubt both institutions might, with profit to themselves, the public, and the profession, be reorganized.

In the coming month the two spring and summer schools will open their sessions. Judging from the experience of the last two years, there can be little doubt that this is the most popular season for medical teaching in Louisville.

At the City Hospital a great deal of interest is created among the students who attend there, on account of the fact that at each clinic-day members of the faculty of two schools hold forth in the two consecutive hours. Professors Roberts, of the University, and Miller, of the Louisville Medical College, constitute the surgical staff for the winter terms, and Holloway, of the Kentucky, and Cartledge, of the Hospital Medical College, compose the staff for the summer terms. Holland, of the University, and Galt, of the Louisville, represent the medical staff for the fall and winter, whilst Marvin, of the Kentucky School, and Wilson, of the Hospital College, perform this duty in the spring and summer. Thus students enjoy the advantages of diverse methods of rival teachers during the whole school year, beginning late in September and extending till the last of June.

One of the most urgent needs at our City Hospital is the establishment of a ward for tubercular patients. In the light of recent investigations, it is wrong that individuals whose power of resistance to infectious disease, whose vitality, is temporarily lowered by suffering, should be constantly exposed to tubercular infection by association with the subjects of that disease. Another need, apparent to the most casual observer, is the establishment of a ward for incurable cases of uterine cancer. In every large hospital are to be found these cases, polluting the atmosphere and disgusting the olfactories of every one necessarily in their presence. The subject of such a disease cannot but feel that her presence is offensive to others, because she is offensive to herself. Among even the most hardened, this consciousness is productive of suffering, and it would be but merciful to allow them the seclusion that their cases demand.

The "constant-immersion" treatment of chronic ulcers, which constitutes a large number of hospital cases generally, has been instituted and maintained for a considerable time by Dr. Cox, one of the internes at the Louisville City Hospital. It is generally conceded that he is meeting with a success above the average by this plan.

In contrast to this, Dr. Marshall, one of his co-laborers, is treating another set of similar cases by the "salicylic-acid dressing." He is not behind his *confrère* in results. In a future communication I shall refer to this subject again.

At the last meeting of the Louisville Medical Society, Dr. W. O. Roberts presented a fibro-cystic ovarian tumor removed the week before from a girl 19 years old. This was his fifth case. Two cases only had died,—one of septicæmia, the other of peritonitis.

Dr. Turner Anderson opened the discussion on "The Treatment of Typhoid Fever." He laid especial stress upon the importance of early diagnosis and early treatment. He advocated the use of opium to produce sleep and to relieve restlessness due to cerebral anæmia, and considered quinine useless, if not injurious, in the course of the disease, only admitting it during convalescence. He favored alcohol in moderation (fʒiij during the day), and expressed disapproval of the specific treatment with calomel and iodine. In hemorrhage he relied upon elixir of opium and a large dose (fʒij) of spirits of turpentine. He did not believe in personal contagion in this disease, but considered the alvine discharges as containing the *materies morbi*. He uniformly disinfects them by the use of copperas and muriatic acid.

ALLEN KELCH, M.D.

PROCEEDINGS OF SOCIETIES.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held December 4, 1884, FORDYCE BARKER, M.D., LL.D., President, in the chair.

IS THE OPERATION OF TRACHEOTOMY IN DIPHTHERITIC CROUP DANGEROUS? WHEN SHOULD THE OPERATION BE PERFORMED?

Dr. JOSEPH E. WINTERS read a paper with this title. He said that the opinion that tracheotomy was a dangerous surgical operation he believed had no valid foundation, and should not be accepted with the confidence with which it seemed to have been received in this hall in March last. He quoted from Mr. Holmes, who represented the operation as a very dangerous one, but said that in one of Mr. Holmes's three fatal cases death was due to what would be called a too nimble tracheotomy, and in another complications arose from inserting the tracheotomy-tube into the cellular tissue outside of the wound, and he regarded comment upon Mr. Holmes's tracheotomies as unnecessary. Prof. Gross, in one part of his work on "Foreign Bodies in the Air-Passages," expressed his opinion of tracheotomy in the class of cases coming under the subject of the paper as very dangerous, and yet quotations elsewhere from the same volume showed that the author was contradictory in his own statements on this point, and it nowhere appeared in this work that he had ever performed tracheotomy for diphtheritic croup. Billroth, some years ago, at a time when there was no evidence that he had performed tracheotomy for diphtheritic croup more than a dozen times, had expressed an opinion that the operation in these cases was a dangerous one; but there was nothing in his more recent writings which would indicate that he any longer entertained this view.

*

The author quoted from numerous writers on the subject of tracheotomy, particularly for diphtheritic croup, some of whom had lived in ancient, some in modern, and some in quite recent times, and in most instances the quotations went to show that tracheotomy in diphtheritic croup was not a dangerous operation. Trousseau had performed the operation two hundred times, without a single accident except in one case, in which the patient died as soon as an incision through the integument had been made. Bretonneau did not speak of the operation as a dangerous one, nor of skill in its performance as necessary to success. Barthez did not regard the operation as dangerous; and quotations to the same effect were made from West, Meigs and Pepper, R. M. Edwards, Mr. Lawrence, J. H. Pooley, Mastin, W. M. Parker, Chambers, etc.

Dr. Winters did not regard the entrance of a small quantity of blood into the trachea as dangerous; on the contrary, many operators recommended that a little blood be allowed to enter the trachea, in order that violent cough might be induced, which would expel viscid mucus and fluids.

The operation of tracheotomy in itself not being dangerous, nothing connected with its mere performance should deter us from resorting to it when indicated. In a large proportion of cases of diphtheria which terminated fatally, death was due to obstruction of the passage of air into the lungs, and the object of tracheotomy was to overcome this difficulty. When the operation failed to save life, generally the reason would be found to lie in the fact that it had been postponed too long a time, in complications existing in the bronchi or lungs, in sudden collapse, in asthenia, or in want of careful after-management. Suppuration in the anterior mediastinum, erysipelas and gangrene around the wound, and slipping of the canula into the tracheal opening had very seldom occurred. Even German writers, as well as others quoted, did not speak of diphtheria of the tracheal wound as more than seldom taking place.

As to the influence of the operation on the cure of croup, the admission of air into the lungs through an artificial opening into the windpipe secured for the diseased larynx entire rest, and thus led to a suspension of the diseased action there. In cases in which the patients had died from other causes than asphyxia some time after the operation had been performed, the pseudo-membrane was found to have disappeared from the larynx; but in cases in which death had taken place within a few hours after the operation the membrane still existed. It therefore appeared that in cases in which the patients got well after tracheotomy the restoration of the larynx to a healthy condition was rapid.

The author said that the diphtheritic process stopped at the level of the vocal cords

more commonly than was supposed, and when it extended into the larynx, trachea, and bronchial tubes it was by direct propagation from above downwards, and not by simultaneous affection of the entire air-passages.

If tracheotomy for diphtheritic croup was not dangerous, if it met the complication of obstruction to the entrance of air to the lungs, and was promotive of cure of the affection, if the specific disease was not aggravated by the operation, and the false membrane very rarely developed at the wound, the operation certainly brought with it no added element of danger; and the next subject which would come up for consideration was that of delay in its performance.

The author then quoted from Trousseau and others to show that a considerably larger proportion of patients upon whom the operation was performed recovered than of those who did not receive the benefits of tracheotomy. He could not conceive of a case in which delay would not be dangerous. We could gain nothing by delay, while the success of the operation would be largely interfered with thereby. When the rima glottidis was obstructed, less air entered the lungs. With every inspiration the lungs became less expanded, the circulation of the blood became embarrassed, imperfect oxidation produced violent constitutional disturbance, the entire body became cyanosed, passive congestion and œdema occurred in the respiratory organs; and yet it had been advised that these immediate precursors of death should be allowed to appear before resorting to tracheotomy. One might with as much propriety postpone herniotomy for strangulated hernia until after the development of gangrene, as to wait until this stage should be reached in diphtheritic croup before resorting to tracheotomy. In the majority of cases of croup the patient died of a want of oxygen. The object of tracheotomy was to render oxygen accessible to the lungs, and every breath of air which the child could take tended towards a cure. We should not, therefore, wait until the patient's strength had been exhausted in gasping and struggling for breath before resorting to tracheotomy.

He would resort to the operation as soon as ipecac and other ordinary remedies failed to produce relief from obstruction to the entrance of air into the lungs by the presence of membrane in the larynx. The tender age of the patient should not contra-indicate the operation, and, as in these cases the disease advanced with much greater rapidity, and as there was greater liability to bronchial and pneumonic complications, the operation should be resorted to earlier.

Prognosis.—Early age, previous ill health, especially chronic catarrh, bronchial and pulmonary changes, made the prognosis more serious, as did also measles, scarlet fever, and nasal diphtheria. When croup came on very early in the disease, making its appearance suddenly and producing marked obstruction, the prognosis was more serious. When the glands of the neck were much enlarged, the operation proved less generally successful. It was an unfavorable sign if the breathing did not become perfectly free and regular after the operation, as it indicated some obstruction below the artificial opening.

After-management.—This was more important than the manner in which the operation should be performed. Careful attention should be given to removing any obstruction to the canula. The patient's powers should be sustained by proper food and stimulants, measures should be adopted for subduing local processes, and attention should be given to the temperature and moisture of the room.

Dr. Winters said the general practitioner should not, in a case of threatening strangulation from croup, search for a surgeon to open the trachea, but should proceed to do it himself without any delay.

The following were some of the conclusions which the author had reached: 1. Tracheotomy of itself, performed with care, involved little, if any, danger to life. 2. Accidents during the operation generally resulted from want of care. 3. It prevented asphyxia, and thus gave more time for the administration of remedies and to enable the system ultimately to throw off the disease. 4. It prevented laborious and rapid breathing, thus tending to prevent exhaustion. 5. It allowed of a free supply of air, and thus assisted in curing the original malady. 6. It was a simple resource by which the condition of the patient was not likely to be rendered worse. 7. Having made a diagnosis, we should not hesitate and delay the operation, as this was the chief cause of failure in unsuccessful cases. 8. Operate slowly, deliberately, and without hurry. 9. Do not lay open the windpipe at one sweep of the knife. 10. It was seldom that either the constitutional condition or special causes contra-indicated the operation. 11. It alleviated suffering. 12. It mitigated symptoms. 13. It prevented complications. 14. It never added dangers to the original disease. 15. Statistics showed that nine-tenths of the cases requiring the operation suffocated without it. 16. No patient who had lived without the operation would have died with it. 17. The dictates of conscience, of facts, and of common humanity united in demanding the operation.

DISCUSSION.

Dr. J. WILLISTON WRIGHT, being requested to open the discussion, said he had never regarded tracheotomy as a specially difficult operation. He was perfectly well aware, however, that, undertaken (as it frequently was) in the middle of the night, in a tene-

ment-house, by the light of a tallow candle or a dirty kerosene lamp, and with such assistance as one could obtain under those circumstances, it was an operation which almost all surgeons approached with some sense of misgiving, especially as it usually occurred under those circumstances in the case of a young child having a short, thick neck and a deep trachea. These difficulties, however, were not so great in his judgment but that they might all be surmounted when they were taken in hand by a man who pretended to understand anything of surgery, coupled with a cool head and a steady hand. The incision itself was certainly a very simple one, involving, as it did, the integument, the fascia, the separation of the muscles on the front of the neck, when the operator reached a mass of connective tissue and veins. These veins, if wounded, frequently bled profusely, and, if the operator was impressed with the hemorrhage which was going on, and undertook to stop all hemorrhage (as was inculcated by many authorities) before opening the trachea, he would probably have a job which would occupy the remainder of the night. If the case was not urgent, it might be proper to stop some of the hemorrhage, even if simply venous. If the incision is made properly, arterial hemorrhage is seldom a troublesome complication in his experience. If, on the other hand, the case were one of emergency, where the great object was to effect an entrance into the trachea as quickly as possible, the child dying of asphyxia, then his custom was always to ignore this venous hemorrhage, and go on into the trachea, feeling very certain, as the speaker of the evening had stated, that hemorrhage would usually stop as soon as the trachea was entered or the tube introduced.

With regard to the entrance of blood into the trachea, he had regarded it as a matter of no special importance. It had, on the contrary, seemed to him sometimes to be the very thing which was needed to stimulate violent expulsive efforts, which would rid the trachea not only of the blood, but also of a quantity of mucus.

In the adult, he regarded tracheotomy as one of the simplest operations in surgery. In the young child it was much facilitated by placing under the back of the neck a common wine-bottle, wrapped in a napkin, allowing the head to hang over it, so as to render the trachea as superficial and prominent as possible.

With regard to the isthmus of the thyroid gland, in operating in emergent cases, in which saving time was the great element, he should be inclined to ignore it altogether, cutting through it with the knife. If time were not an important element, and the gland were in the way and contained a large vessel, he should of course take the precaution to surround the two sides of it with a ligature and divide it between them, as had been indicated by Dr. Winters.

As to the time when tracheotomy should be performed, he thought that, in order to be of much service, it should be done early, and he coincided entirely in what Dr. Winters had said upon this point. He did not think that the operation itself was in any sense a cause of death in membranous croup or diphtheria of the larynx. He was so strongly convinced of the importance of the operation that, if it were indicated and no surgeon were at hand, he would perform it upon himself with a pocket-knife, aided by the hand-mirror.

Dr. A. Jacobi said that much had been written upon the subject of the paper of the evening by many different writers, and Dr. Winters doubtless had recognized the fact that it would be impossible to cover the entire ground in a single paper; that being the case, Dr. Jacobi would limit his remarks to some points brought out in the paper, and would not try to discuss the entire general subject. The paper of the evening was a valuable one, and it would not detract from its value if he should venture to offer some criticisms upon it. The author had quoted extensively from European writers, both ancient and modern, with the principal object in view of showing that tracheotomy was not a dangerous operation, while but very limited reference had been made to American writers, some of whom—as Dr. Day, Dr. Hadden, Dr. Ripley, and others—had written papers containing much useful information upon this subject.

With regard to the dangers of tracheotomy, he thought the principal one was a bungling operation, and by that he meant a bloody operation. Hemorrhage was often due to the operator trying to get through with the operation as soon as possible. Tracheotomy should be performed deliberately, and the isthmus should not be cut through if the operator had as much as two or three minutes' time to spare. Many years ago he lost a case from hemorrhage by going directly through the isthmus into the trachea. The child would not cough up all the blood which had been allowed to enter the trachea. Even in a vigorous patient some of the fluid would be expelled ten, fifteen, or twenty minutes after the operation, and perhaps some of it would never be thrown up. Blood in the bronchi would have the same influence which so much viscid mucus would have in the same position,—namely, to prevent passage of air into the air-cells, which would cause them to contract, the blood-vessels to dilate, congestion, and broncho-pneumonia.

Another cause of danger was failure to administer chloroform. He preferred chloroform to ether, because the child could be brought more quickly under its influence. He knew of cases in which babies had died from struggling in the arms of the nurse,

who had taken them out of bed to make a simple nasal injection.

At what period in croup should the operation be performed? He was certainly of the opinion that after a diagnosis had been made we ought not to wait. He would not limit the operation to cases of membranous croup, but would also resort to it in those cases of laryngitis accompanied by stenosis of a congestive and œdematous type. He objected to dividing croup into stages in these cases, inasmuch as in some instances the operation was indicated quite early in the disease. He would operate in any case in which there was considerable laryngeal stenosis, recession about the supra- and infra-clavicular and ensiform regions, particularly if these symptoms increased in the morning; and if the pulse were becoming frequent and irregular he should say it was high time to operate. He should not ask, in such a case, whether there were membranous obstruction. Could we do anything in cases in which there was constitutional diphtheria or diphtheritic sepsis? He should reply, Most decidedly. He would operate in these cases particularly, because as soon as the trachea was opened the child would cease to breathe the poisonous and fetid odors coming from the larynx and nose.

Dr. Jacobi then directed attention to the use of bichloride of mercury for the prevention of the necessity of tracheotomy in croup.

As to the causes of death after tracheotomy, they might be the same as those which would have caused a fatal result had the operation not been performed; but the principal causes of death after the operation were broncho-pneumonia, œdema of the lungs, and descent of the diphtheritic process.

Dr. J. Lewis Smith said that the older the child, other things being equal, the less the dangers after tracheotomy. It seemed to him that there were two conditions in which tracheotomy was specially dangerous, the one being that state in which the patient was nearly moribund and the surgeon was induced to operate hastily without due precautions against hemorrhage. He thought that in the city, where assistance could always be had, the physician should not undertake the operation alone; but assistance might not always be accessible in the country. He fully agreed with Dr. Jacobi, that the degree of laryngeal stenosis, and not necessarily the presence of pseudo-membrane in the larynx, should govern us in performing the operation. He would divide the cases of membranous croup into two classes, as based upon the necessity for an early or a later operation. If the laryngeal pseudo-membrane in diphtheria developed early in the disease, it would be found to form more rapidly than if it developed, say, at the end of a week, and tracheotomy should be performed immediately; but in the other class of cases the membrane developed more slowly, and there he would try to prevent the necessity for tracheotomy by first using alkaline inhalations, or inhalations of tripsin, and by the internal administration of mercurials. Tubage had been employed with some success in the New York Foundling Asylum.

Dr. J. H. Ripley had been interested in the paper, particularly as the author had taken a position quite antagonistic to that which he had held. The author's ideas regarding the dangers of the operation, its difficulties, consequences, and more especially the consequences of a late operation, were all opposed to his own views. The question was not whether tracheotomy was a difficult or a dangerous operation, but whether tracheotomy in young children for croup was a difficult and a dangerous operation. So far as the operation of tracheotomy in general was concerned, Dr. Ripley would say that it was neither very difficult nor very dangerous. The danger consisted, first, in the condition of the child, and, second, in the necessity for doing the operation within a given time. Dr. Winters, he believed, had touched upon only one danger,—namely, hemorrhage. Dr. Ripley did not regard hemorrhage as the most common cause of death. We had to deal with children suffering from systemic poisoning, stenosis of the larynx, the cellular tissue of the neck infiltrated with the products of inflammation,—sometimes swollen out even with the chin,—and in order to get at the trachea we had to go down, perhaps, two inches, which required a good deal of time and a good deal of care, and before the operation was completed the child was liable to die from syncope; if the stenosis were great, and chloroform were given, the child was liable to die of apnœa; if chloroform were not given, the child would die from struggling. He was willing to go with the small minority, which included such names as Holmes, Gross, and Billroth, and say that he regarded the operation as dangerous. He had performed tracheotomy about one hundred and ten times, and had seen it done by other men about fifty times, and he had witnessed all kinds of complications, and thought he had been the means of saving several lives by being present when inexperienced persons were operating. He had known ten deaths occur on the operating-table, the operations being performed by seven men, four of whom were surgeons of care and experience. He knew of one instance in which the operator plunged the knife into the spinal column; in another it was plunged into the œsophagus, and in a third it was plunged quite through the trachea at one side of the median line.

Dr. Winters had advocated early operations, but, as Dr. Ripley had before said, the man who operated early would have the best success, not for the reasons given by the author, but for the reason that unnecessary

operations were those which were, as a rule, done early. We often have to watch the case closely for two or three days before a differential diagnosis can be made. It was true, as Dr. Jacobi had said, that there were a few cases in which it was necessary to do tracheotomy for stenosis occurring in the course of laryngitis. There were also a certain number of cases of croup which would recover without treatment; and hence it was that there had been so many specifics for this disease.

If late operations were the cause of death, then the causes of death must be those which Dr. Winters had spoken of,—pneumonia, extensive bronchitis, infiltration of the lungs and of the bronchi. But Dr. Ripley thought that if any fact in scientific medicine could be demonstrated it was that incomplete stenosis of the air-passages above the air-cells produced not congestion of the lungs, but anæmia. The air-vesicles were in a state of acute emphysema, and if this were true delayed operations would not prove dangerous on account of broncho-pneumonia, which was liable to follow. The causes of death, according to his observations, were extension of the membrane into the bronchi and consequent suffocation, nephritis and uræmia, respiratory and cardiac paralysis. He did not know that carbonic acid poisoning would cause an extension of the membrane into the bronchi.

Dr. WINTERS, in closing the discussion, said, with regard to danger from blood entering the tracheal wound during tracheotomy, that such danger could be absolutely avoided by properly performing the operation. The scalpel should be laid aside after incising the integument, not to be used again until the tracheal cartilages had been laid bare by careful dissection with two pairs of forceps, dividing any tough bands with dull scissors. He thought the views of Dr. Jacobi regarding the dangers of blood entering the bronchi were those first advanced by Niemeyer many years ago, which were not accepted by advanced pathologists at present, and which were abandoned by Niemeyer himself before his death. If any blood should enter the trachea, it should be removed, together with whatever mucus might be present.

He had not supposed that there was any question of the propriety of using an anæsthetic in tracheotomy for croup, nor as to a choice between chloroform and ether. Another reason in addition to those offered by Dr. Jacobi for preferring chloroform was that ether is irritating to the air-passages.

As to bichloride of mercury, referred to by Dr. Jacobi, he did not believe that it could be introduced into the blood in sufficient quantity to act as a germicide or as an anti-fermentative, and the only influence which it exerted was as a tonic, and for this purpose it would never supersede iron.

As to death from extension of the pseudo-membrane into the bronchi after tracheotomy, he did not believe that any autopsy had ever been made which would tend to show that tracheotomy had caused an extension of the diphtheritic process into the lower air-passages; and in those instances in which the membrane had been found in the bronchi at the autopsy after tracheotomy, death had taken place too soon for the membrane to have developed after the operation.

As to tubage of the larynx, it had been mentioned by Hippocrates. and had been at one time resorted to considerably in France, but had been entirely abandoned.

Deaths on the operating-table were due either to late performance of tracheotomy or to carelessness.

Dr. Ripley's statement that stenosis of the air-passages above the air-cells would not produce congestion with its results would not bear examination. Any one familiar with the physiology of the circulation knew that as soon as there was embarrassment of the respiratory act there was embarrassment of the circulation in the lungs, which caused damming back of blood upon the heart; with lack of aspiration-force from inspiration there was stagnation of the blood in the blood-vessels, and post-mortem examinations in croup showed passive congestion, the accumulation of mucus in the bronchi, pulmonary collapse, and, a little later, congestion of the lungs, pulmonary œdema, and the changes of broncho-pneumonia. Dr. Ripley had also spoken of croup being analogous to asthma and emphysema, but Dr. Winters said that they were not analogous conditions at all. He had found but a single case recorded in which it was claimed that there existed a certain amount of emphysema, the result of laryngeal obstruction, in croup, and in that case it would appear the autopsy had not been made with care.

Dr. LOUIS ELSBERG wished to say that Prof. Gross only taught that tracheotomy under the circumstances in which it was sometimes necessary to perform it—not the ideal operation—was not always free from danger. He heartily sympathized with the general views expressed in Dr. Winters's paper.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, November 13, 1884.

The President, Dr. SHAKESPEARE, in the chair.

Some studies on the micrococcus of the pleuro-pneumonia of cattle. By THOMAS D. DUNN, M.D.

ON September 25, 1883, through the kindness of Dr. Bridge, Assistant State Veterinary Surgeon, and Mr. Thomas Edge, Commissioner of Agriculture of Pennsylvania,

I was invited to be present at an autopsy on some cows suffering from pleuro-pneumonia. Their condition being such that recovery was deemed impossible, Mr. Edge ordered them killed. As a description of the macroscopic and microscopic condition of the lungs was read before this Society a year ago, and as it would have no special bearing on the bacterian nature of the disease, a detailed account will be omitted. Suffice it to say the lung was completely solidified, the air-cells filled with effused blood, serum, and lymph, which usually extended into the small bronchial tubes. Portions of the consolidated lung and blood from the heart were placed in a bottle which had been thoroughly cleansed, and the bottle closed with a ground-glass stopper. These were examined microscopically by Dr. George Martin and myself, and were found swarming with germs,—micrococci. These little bodies, although seen distinctly with a power of 670 diameters, are best studied with a power of 1000. They are colorless, globular or oval in form, outline regular, and refractive power notable. Brownian movement was marked. They did not seem to move independently. They measured from a third to a half micro-millimetre (or from $\frac{1}{8000}$ to $\frac{1}{6000}$ inch) in diameter. They are not dissolved by either alkalies or acids, and take the staining of aniline colors slowly. I have, however, succeeded in staining them by first treating with aqua ammoniæ, then with staining-fluid, and afterwards washing with a weak solution of nitric acid. They have recently been more satisfactorily stained by a two per cent. alcoholic solution of methyl violet. They multiply in nitrogenous culture-fluids at ordinary temperatures by millions. They are generally separate, though sometimes united in pairs and little cellular colonies, forming distinct zoöglœa. From the fact of their being occasionally seen in pairs, it is reasonable to suppose that multiplication is taking place. They resist putrefaction, for the cultivation-tubes started September 26 swarmed with them two months later. When the nitrogenous material is exhausted, their growth is stopped, and they remain in a latent state, as it were, until additional food is given or they are transplanted into fresh fluids. After the tubes stand a few weeks, the membrane formed on the top sinks to the bottom, and the liquid above clears. That they are not dead, but only in a state of repose, is evident from the fact that they multiply anew when inoculations are made from them, but less rapidly than inoculations from more recent cultures.

Dr. J. J. Woodward, U.S.A., presented at a meeting of this Society in 1861 a pleuro-pneumonic lung, and mentioned certain "spores of fungi" found in both the healthy and diseased lung, but he did not describe them. These "spores of fungi" are probably the micrococci under consideration. Aside from this I have not found any record of them, but, unfortunately, I have not had access to the literature pertaining to this subject.

The following culture-experiments were made with the serum virus taken from the diseased lung. The culture-fluid consisted of extract of fresh beef, made by chopping it fine and pouring over it hot water. After maceration the juice was expressed and the extract boiled for several minutes. It was then filtered, and again boiled to thoroughly destroy all germs. It was then placed in culture-tubes which had been washed in a solution of corrosive sublimate, and afterwards boiled. The tubes were closed by absorbent cotton which had been sterilized with corrosive sublimate and the application of dry heat. After the culture-fluid in the tubes had cooled, a minute quantity of the serum was introduced by a small knife whose blade had been heated in a spirit-lamp. The tubes were then placed where the temperature ranged from 90 to 120 degrees Fahrenheit. On examination of these tubes on the 28th, the liquid was found turbid, a thin membrane formed over the surface, and there was a slight deposit. Under the microscope thousands of micrococci were seen. From this cultivation a second was made, and, after standing forty-eight hours, the surface membrane, cloudiness of fluid, and slight deposit appeared, and myriads of micrococci were found. From this a third generation was started, in which appeared a few bacilli, the first discovered.

These are very active, colorless bodies, measuring from three to five micro-millimetres in their long diameters, and from one-third to one-half micro-millimetre in their short. Their movements are at times rapid. Sometimes, after remaining a long time motionless, one will suddenly dart across the field of the microscope, setting many of its fellows in motion, who seem to catch the spirit of the active bacillus. At one time they advance with the rapidity of an arrow, then retreat or describe circular lines. It was noticed in those cultivations in which the bacilli were found that the surface membrane was thicker and more tenacious. In cultivations conducted at a lower temperature the development of micrococci was not so rapid. Fearing that some atmospheric germs might have been introduced with the culture, other cultivations were begun from the second generation, in which no bacilli were found. The culture-fluid was boiled at intervals, to kill germs that might develop from spores not destroyed by previous boilings; and, as a further test, non-inoculated tubes were placed by their side. In forty-eight hours the former were swarming with both bacilli and micrococci, while the non-inoculated ones remained clear for ten days. These subsequently developed germs after inoculation. A second series of observations was commenced with fresh virus, obtained October 4. The first and second

cultures were pure, but in the third bacilli appeared, and in the fourth they had greatly increased. It is difficult to explain the relation these forms bear to each other, whether or not the bacilli are organisms developed from the micrococci: the latter being in a sporal stage of their growth, our investigations will not justify a positive answer. Koch has determined that the bacilli of anthrax develop veritable spores, and they in turn develop bacilli. Several other observers hold this view, and, according to the investigations of Koch, Cohn, and Pasteur upon the development of bacteria, it is probable that the spores of bacilli and other bacteria are identical with micrococci in form, aspect, and behavior towards chemicals. In those diseases in which certain bacilli and micrococci are found to be the virus, it is impossible to distinguish them from harmless ones by their microscopical appearance; that is, a specific disease-germ can only be determined by its effects on living organisms. The micrococcus of pleuro-pneumonia, so far as present observations go, is identical with that of diphtheria, chicken cholera, and the recently-discovered micrococcus of scarlet fever. It is further found that the germ of virulent matter rendered harmless by attenuation does not differ microscopically from the unattenuated which destroys life. I have made no inoculations on animals with the micrococcus of pleuro-pneumonia, but a few cows have been inoculated by others without any reference to a special virus or cultivation of the germ, and the disease was transmitted. However, several experiments have been made, in view of destroying the germ, the results of which I will briefly state. A tube containing cultivated micrococci was boiled, and from it a second was inoculated. In thirty-six hours the tube contained many micrococci, showing that the germ is not destroyed at 212° (F.). A culture-fluid to which had been added ten per cent. of alcohol was then inoculated. No micrococci had developed one week later. One and one-half per cent. of benzoic acid, with borax to dissolve, was then added to a culture-fluid; neither micrococci nor bacilli had appeared six weeks afterward. Another culture was started, to which was added corrosive sublimate in the proportion of one-half grain to the ounce. In three weeks there were no traces of germ-life. To test the influence of cold on these organisms, a tube containing cultivated germs was frozen, and from this sterilized liquids were inoculated. In forty-eight hours they contained myriads of micrococci and a few bacilli. A portion of diseased lung was frozen, and inoculations from this grew in about the same time. It was afterwards found that the cotton which had been sterilized by heat and corrosive sublimate had been inadvertently exposed to old cultivations and decomposing organic substances, and it is possible that bacteria were introduced by it. When I repeated these experiments, it was found that, while inoculations from non-frozen virus develop micrococci in a few hours, it requires several days for sowings from frozen specimens to grow in the same culture-fluid, and under the same conditions of temperature. Whether they were not exposed to cold long enough to destroy the germs, or the influence is only sufficient to render them inactive, further investigations will be required to determine. It is my impression that cold will check the spread of the contagion, but will not destroy it altogether, and that when the disease once attacks an animal cold will have no influence upon it, though it may prevent the spread of the infection to others in the same herd. The power of medicinal agents to control the disease seems to be very feeble. It would appear that corrosive sublimate, alcohol, and benzoic acid arrest the growth of these germs; but whether doses sufficient to destroy them can be administered without endangering life, our veterinary surgeons must determine.

DISCUSSION.

Dr. SHAKESPEARE said that he had read of two attempts within the last year or two to isolate the micrococcus of this disease. Bruylants and Ferree united in an attempt of this kind, and have reported (*Bull. de l'Académie Belgique*, 1880) that they found a micrococcus constant in the pleuritic and alveolar exudate. More recently the report of Poels and Nolen, of Rotterdam, has appeared, in which they describe the isolation and culture of many generations of micrococci. Moreover, they have compared them with those of human pneumonia, claiming their identity morphologically and with regard to their mode of growth, and a further identity as to the results of inoculation, their experiments showing that pleuro-pneumonia in cattle has been produced by inoculation of the cultures of micrococci from human croupous pneumonia, as well as by inoculation of cultures from the pleuro-pneumonia of cattle. The latter report is published in the *Centralb. f. d. Med. Wiss.*, No. 9, 1884.

Dr. FORMAD said that this micro-organism had also been seen and described by Veterinary Surgeon Lyman, who had presented a very elaborate report to the Department of Agriculture. Dr. Quile also, both a medical man and a veterinary surgeon, had worked in pleuro-pneumonia for two years in the Pathological Laboratory of the University of Pennsylvania, always finding the micrococcus present, and in pure cultures kept up for many generations he had not observed any other bacteria. He had inoculated two calves with large quantities of the culture, and had failed, whence he had concluded that the micrococcus was not the cause of the disease. He remarked as a fact in favor of the micrococcus being the cause of the disease that these or-

ganisms are chiefly found in the lymph, and that in pleuro-pneumonia enormous lymph-spaces are developed in the lungs, which are filled with a grumous liquid containing micrococci in large numbers, while the contents of the alveoli contain very few micrococci, but swarm with other bacteria.

Dr. DUNN, in his concluding remarks, said that one point of interest had been omitted in his paper, which was, that the cattle from whom the specimens had been obtained had been first knocked down, then bled to death, and buried superficially in a field through which flowed a stream from which neighboring herds were watered. In a few weeks the disease appeared in these cattle also. As to the literature of the subject, he had not access to sufficient to familiarize himself with any investigations made by others. Some experiments with reference to inoculation have been successfully made in France and England. The lymph was introduced into the body and tail, and was found to protect the animal from the disease. When the virus was inserted into the tail with proper precautions, the mortality from the operation was less, being from one to two per cent. It was also found that when the tail became greatly inflamed it could be removed to limit the inflammation, and still afford protection to the animal. Inoculated animals did not communicate the disease.

A case of old ununited fracture of both bones of the forearm. Presented by CHARLES MEIGS WILSON, M.D.

This specimen was taken from an arm amputated about the middle of the humerus. Eight months previously the girl had fallen from a window and sustained an oblique fracture of the ulna and radius, that of the ulna being about an inch and a half, and that of the radius two inches and a half, below the elbow-joint. The arm was the seat of several large ulcers, and many sinuses were present. The probe detected dead bone. The specimen shows that there has been no attempt at union in the radius, but that the comminuted fragments, being attached to periosteum, have not been destroyed. There has been slight union of the ulna. The cartilages have been destroyed. The joint contained pus, and the internal condyle of the humerus showed a carious condition. The patient made an excellent recovery after the operation.

A specimen of tumor of the bladder was next presented by Dr. J. H. MUSSER.

Case of multiple ovarian fibro-cysts, with subperitoneal fibroids and general (tubercular) peritonitis. Presented by Dr. H. M. FISHER.

Barbara K., æt. 40, married, born in Germany, was admitted into the Episcopal Hospital early in July. Her father died of a tumor in the axillary region, one sister of paraplegia at the age of 16, and one brother and one sister are still alive and healthy. She married early, and had three children. Of these one lived but one day, one died at the age of 12, of "dropsy," and the third (a boy of 18) is still living. Two weeks after the birth of the last child she was obliged to get up and make severe muscular exertion, actually laboring in the fields. Soon after this she noticed that she was losing blood per vaginam, and that she could no longer nurse her child. This bleeding appears to have recurred at intervals of two weeks for a year or more, and often amounted to a positive hemorrhage. Notwithstanding that this was the case, and that she had occasional attacks of severe pain, she continued to work as usual until three or four years ago. Three years ago she came to this country. At about this time she noticed a lump in her left groin, and from this time her abdomen steadily increased in size, she was seldom entirely free from pain, her appetite failed, and her bowels were habitually constipated.

Status Præsens.—Patient is anæmic, and has a careworn, haggard look. Abdomen much distended. Distance from xiphoid to umbilicus two inches greater than from umbilicus to symphysis. Percussion clear over abdomen anteriorly, dull in flanks; fluid moves freely with patient's movements. Hepatic dulness begins in third interspace in mammary line, but not apparently increased in width. Examination of heart reveals a faint systolic apex-murmur. Examination of lungs gives negative result. Much dyspnœa. The dyspnœa becoming urgent, she was (July 14) tapped in the median line, two inches below umbilicus, and eight quarts twelve ounces of a straw-colored fluid rich in albumen were removed. Immediately after the tapping an exceedingly hard mass was noticed in the left iliac region, apparently of the size of a turkey's egg. On the 23d she complained of much pain in the left leg, and the tissues were noticed to be œdematous. This œdema was only slightly relieved by several punctures which were then ordered to be made. From this time till her death patient complained much of dyspnœa, hypogastric pain, and obstinate constipation. She was tapped time and again, and on each occasion a large amount of straw-colored fluid was removed. September 21. Patient had a sudden attack of severe dyspnœa this evening, and died in ten minutes.

The post-mortem examination was made by the resident physician, Dr. J. K. Mitchell, sixteen hours after death, who furnished me with the following notes: "Drew off fourteen quarts of fluid from the abdominal cavity by trocar and canula, all clear and straw-colored. On reinserting canula, a small quantity of dark-brown fluid, looking like beef-tea, came through. The belly-walls were very thin; peritoneum everywhere

much inflamed; whole intestinal surfaces and peritoneum covered closely with small whitish or pinkish points of tubercle; glands not very much enlarged, but very hard; omentum as thick as one's hand, and of an almost wooden hardness and stiffness. Liver and kidneys apparently perfectly healthy. Two cysts in the broad ligaments of the uterus, the larger one about the size of a base-ball or less; one had been tapped by the canula, the other contained about four ounces of the same brown 'ovarian' fluid. The ovaries macroscopically seemed healthy, and the uterus was normal in size and position. The lungs, though much compressed, showed no signs of disease and no adhesions. The heart had also been forced with the lungs upwards, otherwise nothing wrong with it."

A subsequent examination of the specimens brought the following facts to light. The uterus is decidedly hypertrophied, measuring about four inches internally, and appears abnormally hard. Closely attached by false membranes to the lower part of the body of the uterus, upon the right side, there is a hard fibrous nodule of the size of a pigeon's egg. A somewhat larger mass, of similar character, is seen higher up and to the left of the uterus. The right ovary is enveloped in false membranes and closely adherent to the fundus of the uterus. The left Fallopian tube opens directly into the larger cyst of which mention has above been made. This has at its base a fibrous nodule (about two and one-half inches by three-quarters of an inch), which is covered on its under surface by a mass of false membrane. (This is probably the mass that was detected during life in the left inguinal fossa.)

In addition to the cyst above mentioned, there were two other much smaller cysts, but I found it impossible to make out the exact relations of these to the other cysts without making a careful dissection, and this I failed to make. None of these cysts appeared, however, to be connected, as was stated above, with either broad ligament. The left broad ligament was found to be perfectly free; the right was wanting, but appeared to have been removed during the autopsy or subsequently.

The case is a complicated one, but the sequence of pathological events appears to have been the following. The patient, having made severe muscular exertion a fortnight after confinement, is attacked by perimetritis and metritis. This inflammation, at first acute, soon becomes chronic in consequence of the patient being unable to get proper care and the rest that she required. Whether the subperitoneal fibroids from which she was found to have suffered had been already developed at the time this acute pelvic inflammation occurred, it is impossible now to say; but it is probable that they were of later development. Coincident with the periodical hemorrhages and attacks of pain that the patient now suffered from, fresh portions of the pelvic peritoneum are invaded. Finally the peritoneum adjacent to the ovary is reached, and a peri-oöphoritis is the result. The inflammation of the peritoneal investment of the ovary extends, as Heitzmann states, to the ovary itself, causing a proliferation of connective tissue on the cortex of the organ, and from here to the adjacent connective-tissue stroma. In this way the bursting of a ripened follicle may, as he says, be prevented, and a path may be opened for the formation of an ovarian cyst. Supposing this to have occurred in this particular case, we may easily see how the connective-tissue proliferation may have gone on hand in hand, as it were, with the cystic degeneration of the ovary, until the whole ovary was converted into the multiple fibro-cyst that we see in the specimens.

The inflammation extended but slowly from the pelvic to the general peritoneum, probably because the products of inflammation were for a long time in great measure circumscribed by false membranes. Little by little, however, these products were taken up by the lymph-channels, until finally the whole peritoneal surface was infected by them. The occurrence of general peritonitis probably did not antedate much the occurrence of the abdominal dropsy, three years ago, as before that time the patient, though occasionally incapacitated for work by pain, was still able to attend to her usual occupation during the greater part of the time.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held December 10, 1884, Dr. Van Gieson, Vice-President, in the chair.

ROUND CELLED SARCOMA OF THE UTERUS.

Dr. H. C. Coe presented a specimen of round-celled sarcoma of the lining membrane of the uterus removed at autopsy. It was interesting not only on account of the comparative rarity of the disease, but also with regard to the history of the case. The patient, who was over 30 years of age, married, had entered the Woman's Hospital for relief from severe pain in the lower part of the abdomen and frequent uterine hemorrhages. The uterine canal was dilated and curetted, about an ounce of brain-like substance being removed, which was found to be round-celled sarcoma. The woman died of pyæmia on the eighth day after the operation. There were found metastatic abscesses in the lower lobe of the right lung, the largest the size of a hen's egg, and infarctions of the liver and spleen, together with a purulent thrombus of the right iliac vein extending into the vena cava. Dr. Coe was of opinion that sarcoma

of the lining membrane of the uterus was not of so infrequent occurrence as was generally supposed, and said that it was not improbable that a number of the cases of this disease were mistaken for fungous endometritis.

PORTIONS OF THE SCAPULA REMOVED BY OPERATION.

Dr. JOHN A. WYETH presented a portion of the acromion process and spine of the scapula which he had removed for ostitis following traumatism. The point of interest in the case was the fact that complete healing of the wound and recovery took place under one dressing. Antisepsis was observed during and after the operation.

NECROSIS OF THE HEAD OF THE TIBIA.

Dr. WYETH also presented some pieces of bone which he had removed seven weeks previously from a patient 36 years of age, who had received an injury of the tibia in the neighborhood of the knee-joint two years before the operation. There was an ostitis which Dr. Wyeth thought had followed periostitis. It became necessary, in order to remove all of the dead bone, to enter the knee-joint, which was done with great care, protecting the opening constantly during the operation with a piece of iodoform gauze. The patient recovered without any symptom of arthritis, or even of synovitis.

HIP-JOINT DISEASE.

Dr. WYETH also presented all that remained of the head of the femur of a boy who had been suffering for two years from hip-joint disease. He performed exsection with an exsector which he had already exhibited to the Society, and he again spoke in praise of the work done by the instrument. Before the operation the shortening of the limb amounted to two inches, but reformation of bone had taken place to such an extent that there now existed but one inch shortening. Dr. Wyeth stated that exsection for hip-joint disease was not dangerous, and it should be resorted to as soon as invasion of the bone-tissue was evident, and thus the patient would be saved many years' suffering, permanent lameness, and perhaps death. He had never had but one patient die after the operation, and in that instance death took place six months subsequent to the operation, and was due to other causes.

Dr. V. P. GIBNEY remarked, concerning the second specimen presented by Dr. Wyeth, that the case was one of what would be considered as tibial abscess, for which some at the present time performed the operation of trephining, but he thought the treatment adopted by Dr. Wyeth was very commendable, and it showed how timely interference would save the joint from becoming disastrously diseased. He had reported the case of a boy 5 or 6 years of age, who suffered from tibial ostitis, no surgical, and very little mechanical, interference having been made. Finally a cold abscess formed, which ran a long course; the knee-joint became implicated, and he had now white swelling. Further than that, he had recently developed ostitis of the head of the opposite femur. Dr. Gibney felt convinced that, had the operation performed by Dr. Wyeth been performed upon the tibia early in this case, the knee-joint would not have become diseased, and tubercular ostitis of the left hip would have been prevented. He asked Dr. Wyeth why, in the case of his third specimen, it would not have been as rational to resort to the operation of gouging out the bone-detritus as to perform excision.

Dr. WYETH replied that one objection would be that, the hip-joint being deeply seated, it would be difficult to remove all of the dead bone, particularly if it extended below the line of the trochanter. But he was not willing to say that the gouge should never be used on the hip-joint.

Dr. J. H. RIPLEY inquired if it were common to find multiple abscess of the joints in patients who had not a strong diathesis. He thought that prolonged disease in the joint in the case narrated by Dr. Gibney would of itself indicate a strong tubercular or specific diathesis, and, this being the case, there probably would have been subsequent disease of the hip-joint, whether or not an operation had been performed upon the tibia.

A CASE OF SPINA BIFIDA CURED; SUBSEQUENT DEVELOPMENT OF CHRONIC HYDROCEPHALUS AND DEATH BY ASTHENIA.

Dr. V. P. GIBNEY presented the brain and a portion of the spinal cord of a child which was first brought to his clinic on the 11th of July, when it was seven days old. At that time there was a tumor over the coccyx and sacrum, which was of small size, smooth, and perfectly translucent. There was at the end of the tumor a mark which indicated the presence of a partially-healed ulcer. On the 23d of July the tumor seemed to be somewhat larger, and, without examining it by the light-test, Dr. Gibney introduced an aspirator and found pus instead of serum. Dr. Ripley, who saw the patient, was of the opinion that the contents of the sac had become purulent from contiguity to the small ulcer. About the 25th of the month the reflexes of the patellar tendons were exaggerated, and it seemed that myelitis would develop. On the 29th he thrust a bistoury a distance of two or three lines into the tumor, when it seemed to enter a second tumor. After two weeks the tumor became harder, and it appeared that the outer enlargement had collapsed and produced a cure of the spina bifida. There was no further trouble with the tumor, and the patellar reflexes became normal. About a month later, prolapsus of

the rectum occurred, and on the 23d of August the head was noticed to be growing larger. Hydrocephalus rapidly increased, and on the 1st of September Dr. Gibney began a series of aspirations of the cranial cavity, withdrawing at each operation only a small amount of fluid, without producing any unpleasant effects whatever. The last aspiration was performed on the 4th of December, when the needle seemed to strike a somewhat resisting substance. The child died on the 6th of December.

At the autopsy the sac of the spina bifida was empty, but was capable of containing about ten minims of fluid. It was difficult to determine whether or not there had been an abscess over the spina bifida. There was no dilatation of the canal of the cord. Two pints and a half of serum were removed from the cerebral ventricles, which were dilated into one large cavity, obliterating nearly all trace of convolutions. The cerebellum and the medulla oblongata were not involved. The places of entrance of the aspirator-needle were indicated by a few points on the gray matter.

Dr. Ripley remarked that perhaps Dr. Gibney had used the needle too often. Bennet had tapped a hydrocephalic child three times, death taking place after the third operation, and he thought that the tapping had been too frequently repeated. He cited Conquest, who had aspirated in nineteen cases of hydrocephalus. Ten of the patients recovered, and in those cases the operation was repeated only every two weeks. This, however, was an unusual experience.

Dr. Gibney remarked that in his case he at first aspirated every two weeks, but, later, once each week.

Dr. Ripley spoke of two cases of undoubted hydrocephalus in young children, both patients recovering,—one with treatment by aspiration and the other without. In both cases the peculiar hydrocephalic signs disappeared and the cranial sutures united. Although it was commonly supposed that the fluid in hydrocephalus did not become absorbed, it must have disappeared by absorption in these cases.

THE PLACENTA OF ABORTION.

Dr. Hopper presented a placenta of apparently the fifth month of development, which contained a fœtus apparently of the third month. The patient had borne two children, and again ceased to menstruate for three months. The uterus developed for a time, then began to diminish in size. She complained of loss of appetite and general uneasiness, and, after a time, expulsive pains came on and caused the placenta, with a small fœtus, to be expelled.

The Lancaster Crematorium was formally opened November 25.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, December 4, 1884.

The President, R. A. Cleemann, M.D., in the chair.

OVARIAN TUMOR.

Dr. Drysdale presented a polycystic ovarian tumor, which he had removed that morning. He had first seen the patient with Dr. C. R. Prall, May 5, 1884. She was a married lady, 50 years of age, pale, thin, and delicate-looking. She had had eight children, the youngest of whom was then 16 years old. With some trifling exceptions, her menstruation had been perfectly natural until two months before. Since then she had had a constant and sometimes profuse discharge of blood from the vagina, which still continued. She first discovered the tumor in March, 1884.

On examination, Dr. Drysdale found a semi-solid, smooth-walled, globular tumor occupying the lower part of the abdomen and reaching nearly to the umbilicus. It was freely movable, did not fluctuate, but was elastic and a little tender to pressure. Vaginal examination revealed a lacerated cervix. The sound entered the uterus two and a half inches, taking a direction to the right of the tumor. On deep pressure, the end of the sound could be felt at the lower part of the right border of the mass. While the sound was in the uterus the tumor could be moved freely without affecting it. Dr. Drysdale diagnosticated a multilocular ovarian tumor.

By the 5th of June—one month later—it had reached nearly to the ensiform cartilage. From this time it increased rapidly in size, and when it was removed filled the abdomen, pressing the lower ribs outwards. It proved to be a multilocular tumor of the left ovary.

His object in bringing it before the Society was to obtain an opinion from the members as to the cause of a phenomenon which was observed in the early stage of the growth. At the time the patient first noticed the enlargement, she found that when she would lie on her right side the tumor would ascend to the left, and when on her left side would rise to the right, as if lighter than the surrounding parts. She informed Dr. Prall of this, and he naturally supposed she was mistaken, but a careful examination of the tumor while she changed her position verified her assertion. As the mass increased in size this peculiar change of position ceased, and when the abdomen was opened nothing could be found to account for the irregular behavior of the growth.

Dr. Parvin inquired about the length of the pedicle and the weight of the tumor.

Dr. J. C. Da Costa has a case under obser-

vation in which the condition of great mobility is present.

Dr. DRYSDALE replied that the pedicle was extremely short. The tumor weighed thirty-five pounds, and was multilocular in character. At the time of its removal he could not determine any fluctuation. Every parovarian cyst is movable in its early stages. He intended to call attention to the peculiar and, to him, unaccountable motion of this particular cyst.

HYDROCHLORATE OF COCAINE.

Dr. CHARLES MEIGS WILSON presented the histories of three cases in which the hydrochlorate of cocaine had been used in operations with the hope of obtaining local analgesia, and reported negative results.

MALIGNANT CYSTIC DISEASE OF OVARIES.

Dr. D. LONGAKER exhibited the specimen, with the following history. The subject from whom this specimen was removed was a German woman, 63 years old. She had been married the last twenty-seven years of her life, and was sterile. During the last five months she was under the care of Dr. Jos. S. Gibb, of this city, at whose request I first saw her, and by whose kindness I am enabled to report the case. The menopause was established at 53,—ten years ago. The patient had always enjoyed fair health, but four years ago she again began to have a bloody discharge from the vagina. For this she consulted a doctor, and was soon well again. The date of the onset of her last illness was indefinite. It was insidious, and the particular symptom for which she desired relief was inability to micturate. This was found to be due to suppression of the secretion of urine, as the bladder was empty. There was also decided interference with nutrition; her appetite and strength failed rapidly. The urine was found to contain a very small amount of albumen. She had occasional nausea and bilious vomiting and diarrhœa. She suffered with pain in the left side of the abdomen. On examination the doctor discovered a hard tumor (nodulated) to the left of the uterus, projecting upwards into the left inguinal region. It was adherent, and but slightly movable.

She was first seen by me on October 6. At this time she was in bed, suffered from orthopnœa, and was unable to rest or lie down. Her abdominal cavity was greatly distended by a fluid which had accumulated rapidly in the previous three or four weeks. Œdema of the ankles had been noticed a few days before. Her general appearance was decidedly anæmic and cachectic. The abdomen was very tender to palpation, especially over the left inguinal and hypogastric regions. The flanks were bulging, and were flat on percussion. The tumor could be indistinctly outlined, immobile, lying in contact with the left ilium, dipping down into the true pelvis behind and to the left of the uterus, and distinct from it. The cervix had undergone senile absorption, but from the os externum a small polypus was found hanging in the vagina.

October 7 she was tapped. A large bucketful of a brownish-red fluid, of specific gravity 1020, was removed. On microscopic examination it was found to contain blood and various corpuscles and epithelium (the ovarian cell was not found). It contained paralbumin.

A more careful examination now revealed a circumscribed, clearly-defined, firm, nodulated growth in the region already indicated. It was found adherent, and could be only slightly displaced. It was of the size of a large fist. Palliative treatment was continued, but the patient's condition gradually grew worse. There was again a slight accumulation of fluid in the abdominal cavity. She was subject to attacks of bilious vomiting and diarrhœa, alternated with constipation. There was no apparent increase in the size of the tumor, and during this period pain was not a marked symptom. At no time was there acute suffering. She died of exhaustion, November 27.

Autopsy was made the next day by Dr. Gibb, in the presence of and assisted by Dr. E. W. Holmes and myself. The subcutaneous fat had been almost entirely absorbed. The parietal peritoneum was covered with lymph, with numerous nodular elevations in various stages of organization. The intestines had contracted numerous adhesions. The capsule of the liver was one-eighth of an inch thick. In the mesentery there were also deposits of lymph, some of which were more recent and less organized. The abdominal cavity contained about two quarts of fluid, the same as that already described.

On the left side, extending two inches above the pelvic brim, was found a tumor apparently solid, but which, on close examination, was found to be cystic. One of the largest of the cysts had ruptured; the opening was found at the posterior-inferior portion of the growth. It was not recent. The capacity of the emptied cyst was about four ounces. The tumor dipped down into the true pelvis between the broad and utero-sacral ligaments of the left side. It was very adherent, and was removed with great difficulty. On incising and freely opening the cyst, some coagulated fibrin was found,—the remains of a hemorrhage into the cavity. When it was entirely removed it was found to arise from the left ovary. The oviduct was slightly dilated, and its fimbriated extremity was adherent to and spread out over the tumor.

On the right side, in the broad ligament there is a cyst slightly larger than the tumor.

Its contents are dark and very dense; it is very heavy. The cyst is surrounded by a dilated Fallopian tube containing a clear, transparent fluid of a bluish-white hue. At its widest part it is an inch in diameter. Behind and below this cyst is found the right ovary; it is adherent, flattened out, and seems continuous with it. The entire specimen was carefully dissected out as it is shown. From its rapidly-fatal tendency, with the macroscopic appearance of the tumor, there is very little doubt that a microscopic examination will reveal it to be malignant. Though perhaps possessing the greater pathological interest, there are also a few points in the case which may concern us in regard to diagnosis and treatment. Study of the fluid at first caused a suspicion that it came from a cyst; its high specific gravity and the chemical tests to which it answered favored such a view. But this was entirely at variance with the history of rapid accumulation and absence of physical signs indicating the existence of a large cyst. It was apparent at the autopsy that an attempt at extirpation could only have hastened the fatal result.

The specimen was referred to a committee for further investigation.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Meeting of November 24, 1884.

Discussion on the Third Stage of Labor.

Dr. W. M. POLK, being requested to open the discussion, said that he heartily agreed with the author of the paper* in saying that we were not in a position to discard Crédé's method. It seemed to him that the method had been so rich in good fruits since its introduction into America, as shown by statistics, that its advantages were placed beyond controversy. He certainly had never seriously contemplated abandoning it in any respect, and he could not understand how any practitioner of experience could once claim that Crédé's method should be relegated as a piece of useless rubbish. There were one or two points, however, in the paper to which he must take amiable exception. For instance, ceasing the administration of chloroform at the close of the second stage, or as the child's head began to distend the perineum, seemed very improper, as this was just the time when the patient most felt the need of the anæsthetic, and he thought the damage which pressing the chloroform at this moment might do would be fully compensated for by the relief which it would give the patient. Of course every one knew the danger of producing inertia of the uterus, and this danger had appeared to him to be so great that he had at moments almost contemplated never using the agent again, but when he did employ it he continued its administration until the head was virtually expelled.

He further disagreed with the author with regard to non-twisting of the membranes. He had seen no harm come from the practice, and he thought it might do good. If within five minutes after delivery of the child the uterus did not show a tendency to contract and expel the placenta, he thought it our duty to begin to practise Crédé's method; and if after the lapse of from half an hour to three-quarters of an hour by this method the membranes were not expelled, he should regard the case as a pathological one.

Dr. Baruch inquired of Dr. Polk what had been his experience with reference to expulsion of the placenta into the vagina shortly after the second stage of labor among the women of higher social life.

Dr. Polk replied that he had found experience to vary in this matter, depending upon the health and strength of the woman. In weaker women the placenta was liable to be retained within the os, while in the stronger, whatever might be their social standing, it would probably be expelled.

Dr. Robert A. Murray believed with Dr. Baruch that no method would take the place of Crédé's in cases demanding its use, but he believed also that nearly all the physicians in New York City practised a method which was superior to Crédé's in the large majority of cases of midwifery. It was taught, he believed, by all, or nearly all, professors of midwifery in the city that after the second stage of labor had been completed the physician should retain the hand upon the uterus, aiding in its contraction, until the organ has assumed permanent contraction. If this were done, the true expression method of Crédé would be applicable only in cases in which hemorrhage was threatened after the use of chloroform, or after extreme exhaustion of the patient from prolonged first stage, powerless second stage, or instrumental delivery. He practised twisting of the membranes.

Dr. J. H. Fruitnight agreed with the author as to the advantage of placing the hand against the external vaginal orifice to guard against too rapid expulsion of the membranes. He considered twisting of the membranes a proper procedure. Out of six hundred and fifty cases of midwifery, he had had retention of the membranes in one case and post-partum hemorrhage in three or four. He regarded the placenta after delivery as a foreign body, which should be expelled from the cavity of the uterus as soon as practicable.

Dr. Irwin thought the paper gave one the impression that the Dublin school and the English physicians interfered in the third stage of labor more than they do in fact. He spoke from his experience in the hospi-

* Paper by Dr. Baruch: see page 216, *ante*.

tals and attendance on societies at which this subject had been discussed. He thought he was not mistaken in his recollection that their practice was usually to adopt the expectant plan. At the same time, however, they would not exclude active assistance, especially in cases which seemed really to call for it. They did not object to the removal of the placenta when it lay loose in the vagina, and they favored twisting of the membranes, but not pulling upon them.

Dr. MALCOLM MCLEAN directed attention to the importance of having a clean vessel at hand into which to cast the placenta, in order that it might be examined carefully with regard to whether a portion of it may have remained in the uterine cavity.

Dr. BARUCH, in closing the discussion, said, with regard to Dr. Polk's statement concerning the use of chloroform, that he recognized the desirability of lessening the patient's sufferings, which were very intense at the close of the second stage, and for that reason he continued its administration, in cases which demanded the employment of the anæsthetic, up to a moment before the delivery of the child. His only objection to twisting the membranes was that there was a temptation and a liability to make some traction during the procedure, and this would favor tearing.

REVIEWS AND BOOK NOTICES.

A TEXT-BOOK OF PRACTICAL MEDICINE. Designed for the Use of Students and Practitioners of Medicine. By ALFRED L. LOOMIS, M.D., LL.D. With Two Hundred and Eleven Illustrations. New York, William Wood & Co., 1884. 8vo, pp. 1102.

This work traverses the usual field of internal pathology considered in text-books upon the practice of medicine, but it does so with evidences of such unusual discretion and skill as to present the subject in a fresh light and to constitute a most acceptable addition to medical literature. The illustrations are abundant, original, and, as a rule, neatly drawn, and well illustrate the text, in which the subjects are discussed in the light of the most recent additions to our knowledge of pathology and therapeutics. The work is characterized throughout by temperate statements with regard to vexed questions in pathology, shown particularly in the consideration of the several zymotic diseases, and in the suggestions for treatment it is a safe guide. The pages do not bristle with ready-made formulæ and specifics for various symptoms, and on this account will probably be more acceptable to those who know the fallacies and dangers of dogmatism in therapeutics. For students this will probably be regarded as the best American text-book of practical medicine that has recently appeared.

A TEXT-BOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN J. REESE, M.D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania, etc. 8vo, pp, 606. P. Blakiston, Son & Co., Philadelphia.

Medical jurisprudence is as yet an undeveloped, or perhaps it would be more accurate to say an undifferentiated, specialty in this country. While a fair number of medical men have sufficient knowledge on individual topics, such as insanity and poisonings, there has as yet been no attempt to cultivate the science in connection with our medical colleges to such a degree as to produce medical jurists commensurate in knowledge with the ophthalmologist, gynæcologist, and other specialists in practice. That this is a serious error in medical education is admitted. It arises partly, perhaps, from the lack of material for the practical instruction on the topics involved, partly also from the rather ponderous character of the literature of the science.

The work before us is a step towards attracting students to the study of medical jurisprudence and toxicology. The author has been long known in the field to which it is devoted, and he brings to bear in its production large experience as an expert and as a teacher both to medical and legal students. A careful examination of the book bears out these expectations, and we are pleased to learn, from a perusal of the journals, that it has been everywhere favorably received.

The work covers the entire subject, a large amount of the space being given to toxicology. The style is clear and condensed, and the arrangement of the matter satisfactory. The absence of illustrations can hardly be considered a defect, because the facilities of chemical and microscopical investigation are at the present time so great that any interested student can prepare specimens for himself, and such preparations will be of much greater practical value than any schematic illustrations.

It is to be hoped that the work will find favor in the eyes of those whose duty it is to guide the studies of medical students in the departments of toxicology and jurisprudence.

GLEANINGS FROM EXCHANGES.

REMOVAL OF RIGHT KIDNEY.—At Milan, on June 8, Prof. Bottini extirpated a kidney under the following circumstances. A. M., 27 years of age, had had two calculi removed by lithotomy fifteen years before. Three years after the operation an abscess formed and discharged in the iliac fossa, and then reappeared in the lumbar region, where it was opened by the use of caustic potassa, which was followed by a permanent fistula.

Having decided to remove the kidney, Prof. Bottini, operating under strict antiseptic precautions, made a vertical incision along three inches outside the quadratus lumborum muscle. The kidney was isolated, the renal artery was secured by one ligature, the vein and ureter by another. A drainage-tube was introduced after the space had been cleared and bleeding stopped. The sinus was incised, and its walls united by sutures. The dressings were renewed daily, the drainage-tube was gradually shortened and entirely removed on the eighteenth day. Temperature was 100° on the second day, and soon became normal again. Urine was secreted in proper quantity, without pain, and gave no deposit. The patient went home on the eighteenth day, with the wound nearly healed. Upon examination, the kidney was found to weigh forty-eight grammes. It was the site of chronic pyelonephritis, and two small calculi were found in its dilated pelvis.

Poisoning by One-Fourth Grain of Morphine.—At a meeting of the Cincinnati Academy of Medicine, Dr. Thad. Reamy reported a case of fatal poisoning from one-quarter of a grain of morphia sulphas. The patient was a well-nourished lady of twenty-eight years of age. Dr. Reamy had operated under ether, at the Good Samaritan Hospital, for laceration of the cervix uteri and perineum. The operation lasted thirty minutes, and the patient came nicely out from under the anæsthetic in another half-hour. About an hour after the operation, the patient in the mean time having been conversing with friends, pain was complained of, to relieve which Dr. Hirons, the house-physician, administered one-fourth grain of morphine hypodermically. In about one-quarter of an hour the pain subsided. Dr. Hirons visited the patient again in about an hour, when he found her semi-comatose, with contracted pupils, slow respirations, and feeble pulse. The usual restoratives were administered by Dr. Hirons, Dr. Reamy (who was hastily summoned), and Dr. Mitchell (who happened in). The patient sank gradually, and died in about eight hours.

In commenting on this case, Prof. Nickles criticised the treatment in that not enough atropine was given. One-ninety-sixth of a grain had been given with the morphine. This amount of atropia was twice repeated, and afterwards one-twentieth grain was given. Prof. Nickles said that it should have been given in one-sixteenth-grain doses every ten or fifteen minutes until the breathing was increased in frequency.

The patient had never taken morphine before, and her peculiar idiosyncrasy was never before discovered.

The Pathology of Myxœdema.—Dr. W. B. Hadden (London), in a paper on this subject (*Proceedings of the International Medical Congress*), said that myxœdema is a disease characterized by a general swollen condition of the body. The appearance of the patients suggested ordinary dropsy, but the parts did not pit on pressure. The face was swollen and puffy, the lips and alæ nasi thickened, the eyelids œdematous-looking, and on each cheek there was a well-defined flush. The general expression was placid and inert,—in a word, cretinoid. The skin everywhere was dry and harsh; perspiration and the secretion of the sebaceous glands were almost absent. The hands were broad, clumsy, and spade-like. The hair was soft and scanty, and tended to fall out. The nails and teeth shared in the general mal-nutrition. The thyroid gland wasted, although it was difficult often to determine this, in consequence of the swelling of the tissues of the neck. Soft masses were usually to be felt in the supra-clavicular regions. The temperature was almost constantly subnormal. The speech was slow, thick, monotonous, nasal. The tongue seemed to be too large for the mouth. There was general muscular feebleness. The gait was slow and tottering, and all movements were retarded. There was marked mental lethargy. An indisposition to all bodily and mental activity was one of the most striking features of the disease. The urea excreted by the urine was much diminished, but, with this exception, there was no constant change. In the latest stages albuminuria and true dropsy might supervene. Somnolence, insanity, impairment of memory, disorders of the special senses, and certain subjective sensations, were frequently experienced. The tongue, uvula, soft palate, and larynx were generally swollen, and difficulty in deglutition was often observable. The appetite was bad, and defecation usually difficult, in consequence, probably, of swelling of the mucous membrane of the rectum. The disease usually attacked adult women, but it occasionally commenced before the age of twenty, possibly sometimes in childhood. It occurred among rich and poor. Climate and race were probably without influence. Syphilis and excess of alcohol had no share in its causation, but permanent mental disturbance and exhaustion from excessive child-bearing were occasional antecedents. As regarded family history, phthisis was remarkably frequent, acute rheumatism and insanity occasional, and in at least one case myxœdema had been observed in the collateral relatives. As to morbid anatomy, the constant factor is a diminution in size of the thyroid gland. According to Dr. Ord, there is solid œdema of the connective tissue throughout the body, and a great increase in the amount of mucin; hence the name myxœdema. The author believed that the disease was probably dependent on change in the sympathetic nervous system, and he thought it not unlikely that the thyroid was in some

relation with the peripheral sympathetic nerve-fibres. This view has recently been borne out by post-mortem evidence. He had seen improvement occasionally from the medical treatment, but especially from jaborandi.

UNUSUAL CAUSE OF INTESTINAL OBSTRUCTION.—A patient who was lately under my care, suffering from chronic obstruction in the intestinal canal, probably in the descending colon, took, on his own account, freely of charcoal powder—often a drachm a day—to relieve flatulency. The result was an all but fatal obstruction. Fortunately, under the use of enemata, coupled with persistent but gentle abdominal friction, relief was obtained, although stercoraceous vomiting once occurred. The excretions causing the obstruction were coated with carbon, and portions of carbon also passed in the free state. This is the second case in my practice in which charcoal powder has caused intestinal obstruction.—DR. RICHARDSON: *Asclepiad*, October, 1884.

MISCELLANY.

NATIONAL HEALTH LEGISLATION BEFORE CONGRESS.—We are indebted to Dr. Gihon, President of the American Academy of Medicine, for a copy of the bill entitled "An Act to Prevent the Introduction of Contagious and Infectious Diseases into the United States, and to Establish a National Board of Health," which was prepared by a Committee of Conference of the State Boards of Health held recently in Washington. The bill has been presented by the Committee on Federal Legislation to the Committee on Public Health of the National House of Representatives, and has a good support from individual members. In view of the prospect of a cholera epidemic, the need of such a board is evident, and, if created, it will be able to demonstrate its usefulness, unless fatally hampered by influences emanating from the Marine Hospital Service.

AN AMERICAN SOCIETY OF PUBLIC ANALYSTS was organized in Brooklyn on the 24th of last month, by representatives holding appointments under the Boards of Health in the several States of the Union. Its objects will be, by frequent meetings, the discussion and publication of papers, etc., to advance and disseminate knowledge regarding adulteration of food or drugs, to secure uniformity of results, and to provide for efficient sanitary control over the food-supply. A meeting was held December 8 for the election of officers.

WOMEN MEMBERS OF MEDICAL SOCIETIES.—Dr. Osborn was recently elected to membership in the Academy of Medicine of Cincinnati, she making the fourth female member. These four lady-physicians are fairly active members of the Academy.

NOTES AND QUERIES.

OBITUARY.

DR. HARVEY L. BYRD, of Baltimore, died in that city, November 29, in the sixty-fifth year of his age. He was a graduate of the University of Pennsylvania, and also attended lectures at the Jefferson Medical College, and revived the Medical Department of the Washington University and was the dean of its faculty for five or six years. He at this time joined several others in forming the College of Physicians and Surgeons of Baltimore, in which he was the president of the faculty and at different times held several professorships. He was editor of the *Oglethorpe Medical and Surgical Journal* for three years, and contributed a number of articles to the medical press. He was a member of several medical societies. At the close of the war, during which he served as surgeon in the Confederate army, he went to Baltimore.

HENRY A. MARTIN, M.D., M.M.S.S., of Boston, died December 7, 1884, at his home in that city.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM DECEMBER 7, 1884, TO DECEMBER 20, 1884.

HAMMOND, JOHN F., COLONEL AND SURGEON.—Retired from active service, by operation of law, on December 7, 1884, under provisions of Act of Congress approved June 30, 1882. S. O. 287, A. G. O., December 8, 1884.

MCKEE, JAMES C., MAJOR AND SURGEON.—Leave of absence still further extended one month. S. O. 288, A. G. O., December 9, 1884.

LAUDERDALE, JOHN V., CAPTAIN AND ASSISTANT-SURGEON.—(Fort Sully, Dakota Territory.) Granted leave of absence for one month, to take effect about December 20, 1884. S. O. 146, Department of Dakota, December 9, 1884.

COMEGYS, E. T., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 234, Department of Missouri, December 8, 1884.

PORTER, JOSEPH Y., CAPTAIN AND ASSISTANT-SURGEON.—Sick-leave of absence extended four months, on surgeon's certificate of disability. S. O. 286, A. G. O., December 6, 1884.

KANE, JOHN J., CAPTAIN AND ASSISTANT-SURGEON.—From Department of the East to Willet's Point, New York. S. O. 286, A. G. O., December 6, 1884.

BANISTER, J. M., CAPTAIN AND ASSISTANT-SURGEON.—(Fort Adams, Rhode Island.) Granted one month's leave of absence, on surgeon's certificate of disability. S. O. 251, Department of the East, December 9, 1884.

PILCHER, JAMES E., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Ordered to Fort Custer, Montana Territory, for duty. Order assigning him to duty at Fort A. Lincoln, Dakota Territory, amended. S. O. 145, Department of Dakota, December 8, 1884.

GRAY, CHAS. C., MAJOR (retired).—Died at Geneva, New York, November 22, 1884, instead of November 26, as heretofore announced. Circular Orders, A. G. O., December 8, 1884.

LIST OF CHANGES OF STATIONS OF NAVAL MEDICAL OFFICERS FROM DECEMBER 7, 1884, TO DECEMBER 20, 1884.

P. A. Surgeon T. C. CRAIG, detached from "Alliance," and placed on waiting orders, December 6, 1884.

Assistant-Surgeon L. W. CURTIS, to the Naval Hospital, Chelsea, December 9, 1884.

P. A. Surgeon J. H. GAINES, present duty continued.

P. A. Surgeon E. H. GREEN, special duty at Museum of Hygiene, Washington, December 11, 1884.

P. A. Surgeon J. M. MURRAY, detached from Naval Hospital, Chelsea, to the Flag-ship "Hartford," December 9, 1884.

Surgeon T. WOOLVERTON, to the "Shenandoah," December 6, 1884.

Medical Inspector D. KINDLEBERGER, detached from the "Hartford," and placed on sick-leave.

PHILADELPHIA, JANUARY 10, 1885.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON PERICARDITIS, PROBABLY THE RESULT OF TRAUMATISM; AND ON THE TREATMENT OF PLEURISY.

Delivered at the Philadelphia Hospital

BY EDWARD T. BRUEN, M.D.,

Physician to the Hospital, and Demonstrator of Clinical Medicine in the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M.D.

GENTLEMEN,—I propose to-day to call your attention to this man, who was admitted to the hospital six days ago. The patient stated that he had been injured in a railroad-accident about seven weeks ago. He was jarred between the seats in some way, but did not notice any special inconvenience, beyond the general shaking up, until two or three weeks later, when pain in the præcordia, cough, and dyspnœa appeared, and these have continued up to the present time.

Upon admission, he complained of marked shortness of breath, a dry cough, with a severe pain in the chest, which was rather more marked over the præcordia than elsewhere, and radiated around to the left side. His temperature, which was 99° on admission, went up to 102° the same evening. Since then the temperature has ranged between 99° and 101°. On admission, the pulse was about 100 per minute, and slightly dicrotic.

Our interest, of course, centres in the diagnosis, and naturally the seat of the pain and the dyspnœa attract our attention to the chest. Percussion of the chest shows marked flatness over the region of the heart. Above the second rib there is dulness. The first clinical point to which I call attention is the recognition of the difference between dulness and flatness. By contrasting the flatness obtained over a perfectly non-resonant mass with the dulness obtained over a partially resonant area, we may be tempted to call the dulness good resonance; but by contrasting the dulness with the percussion-note heard over a normal portion of the chest, its true quality is recognized. In the left axillary region there is resonance, and also posteriorly from the top to the bottom of the chest. The right side is everywhere resonant.

Listening over the right side of the chest, I recognize an exaggerated respiratory murmur. Over the left side posteriorly a respiratory murmur is heard, which is vesicular, although feeble. If the patient take a forcible inspiration, you might call it feeble bronchial breathing, but it still has the vesicular element. It is not quite harsh enough to be properly called bronchial breathing, nor is the expiratory sound high-pitched. Auscultation during quiet breathing gives a very faint respiratory murmur, so faint, indeed, that you might infer that there was absence of respiratory murmur. Auscultation of the præcordia reveals very feeble, indistinct heart-sounds. The word "distant" is the proper one to convey the muffled character of the sounds, which are without murmur. The same muffled character of the sounds can be reproduced by placing a layer of cotton over the healthy heart. Examination of the præcordial and epigastric regions by inspection shows the existence of a pulsation; but, adding palpation to inspection, we find that the apparent pulsation in the epigastrium is merely a transmitted vibration. Examination of the præcordia by inspection shows that there is prominence of this region. Inspection of the chest shows that while the right side moves distinctly in respiration, the left is perfectly quiet.

What shall be our diagnosis from the signs which have been elicited? Evidently some one had made the diagnosis of pneumonia or pleurisy before he was admitted to the hospital, for his back bore the marks of cups. The question of pneumonia can, I think, be readily dismissed. In the first place, there is no bronchial breathing at any part of the chest. In the second place, the only area of dulness is in front over the præcordial region. If this dulness had been on the right side, we might have attributed it to consolidation of the middle lobe of the right lung; but, as the left lung has no middle lobe, this idea can be dismissed. The flatness is over the præcordia, and not over the lung proper. Again, it is impossible to suppose that the man has had pneumonia for four weeks and not present any more positive signs to-day.

The question in regard to pleurisy is

not so readily disposed of. In favor of pleurisy we have the feeble respiratory murmur and the diminished movement of the left side, while, on the other hand, there is exaggerated respiratory movement, exaggerated respiratory murmur, and increased resonance of the right side. All these signs, of course, indicate that the left lung is disabled. Having excluded consolidation of the lung, it would seem probable that pleurisy exists. At the same time there is one strong point against the idea of pleural effusion, and that is the resonance on percussion over the left chest. This excludes pleurisy as a general condition, but it does not exclude a localized pleural effusion. Flatness on percussion is almost always due to the presence of fluid. I think that it may be said that the sound given by pulmonary consolidation is always dull, while the sound given by a collection of fluid is always flat. We, however, dismiss the idea of a sacculated pleural effusion, partly by exclusion, and partly by means of another line of reasoning, to which I shall refer in a few minutes. A localized pleural effusion in the region of the præcordia would be very unusual. Occasionally a localized effusion occurs at the apex, but even this is rare. I recall one case, exhibited last year at the University Hospital clinic, in which a localized empyema occupied the space between the third rib and the clavicle on the right side. Such effusions usually occur posteriorly, and not anteriorly. Therefore, if we have any more satisfactory explanation of these physical signs, we have good grounds for excluding sacculated pleurisy.

The area of flatness and the muffled heart-sounds point to some lesion of the pericardium. We may have fibrinous inflammation of the pericardium, in which both the heart and the pericardium are covered with fibrinous exudation. We may also have a serous inflammation of the pericardium, in which serous fluid is thrown out. These conditions are analogous to fibrinous and serous inflammation of the pleura. When the pericardial process is developed slowly, it is more common to have the fibrinous form of the exudation in excess. The history of the case and the physical signs would point to such a condition. Pericarditis, however, never develops spontaneously, like pleurisy. In a large proportion of cases, probably two out of every three, it develops in consequence of rheumatism. I have carefully investigated the history of this patient, but can find no evidence of rheumatism. This is a great point against the diagnosis of pericarditis. After rheumatism, the largest number of cases are associated with chronic Bright's disease. There is no Bright's disease in this case, so far as can be made out from the examination of the urine and of the general condition. The next most frequent cause of pericarditis is some disease of the lungs or pleura, more particularly the latter. We have already said that there is no reasonable ground to believe in the existence of pleurisy. Some cases of pericarditis are produced by tubercle, and a few cases by cancer, but these conditions are readily excluded in this case. Then we have sometimes abscess of the liver perforating the chest and producing pericarditis. These are all indirect causes. We have said that the patient has no rheumatism, no Bright's disease, no affection of the pleura or lungs; he has no tubercular disease nor malignant disease; there is no abscess of the liver, and no peritonitis. Having excluded these causes of pericarditis, how is the condition, if it does exist, to be explained?

I attribute it to the injury, for direct local injury will account for a small fraction of the cases of pericarditis not accounted for by the causes already enumerated. If this were a case of ordinary pericarditis, could it develop in this slow, latent way?

One reason for bringing this case before you is because this disease will be frequently overlooked unless the physical signs are carefully considered. This is an affection which is chiefly recognized by the physical signs. The symptoms are, as a rule, indefinite and not sufficient to allow any one to make a diagnosis without a careful physical examination. This man is suffering from dyspnœa, but this is not so severe as to make one suspect that the cardiac sac was the seat of inflammation. Occasionally there is violent dyspnœa and the delirium of which you read in the text-books, but usually the cases of pericarditis seen in actual practice closely resemble the one before you.

In this case, if we conclude that our patient is suffering from pericarditis, we must explain the occurrence of the pul-

monary symptoms. This can be easily understood if the anatomy of this region is recalled. The pericardium rests on the large bronchial tubes, and if effusion occur into the pericardial sac pressure is exerted on the bronchial tubes of the left side and air is prevented from entering the left lung. I am disposed to account for the feeble breathing and the absent respiratory movements by the pressure of the pericardial sac—enlarged as it is by the inflammatory process—upon the bronchial tubes, and I am inclined to regard the dulness which is present at the apex of the left chest anteriorly as due to the partially-inflated lung, just as we explain the dulness in the hypostatic congestion of typhoid fever. All the respiratory symptoms may be ascribed to the pressure of the pericardial sac upon the bronchial tubes. The heart itself is probably drawn back into the pericardial sac, and this apparent pulsation in the epigastrium is nothing but a tremor transmitted from the heart. I think that the position of the heart, when there is pericardial effusion, is often misapprehended. In one case, and the only case in which I have tapped the pericardial sac, a distinct pulsation was felt in the position of the apex, and I introduced the trocar with fear and trembling lest I should strike the heart. Examining as well as I could with the canula in the pericardial sac, I found that the heart was crowded over somewhat to the right and into the upper part of the sac. The pulsation which I had felt had been transmitted through a layer of fluid. In this case you recollect that we made the diagnosis of fibrinous, not serous, pericarditis, and the effusion, though extensive, is not as large as frequently observed.

What shall be done for the patient under these circumstances? The treatment of pericarditis depends altogether upon its cause. If in a case of articular rheumatism the symptoms of pericarditis make their appearance, you will simply continue the treatment of the rheumatism. If that is the alkaline treatment, you simply push the alkaline remedies. As you are aware, there are two plans of treating rheumatism,—the method with large doses of alkalies and the method with the salicylates of sodium or ammonium. I might expand this idea of the treatment of rheumatic pericarditis so far as to say that the salicylates are useful in rheumatism to control two symptoms,—the pain and high temperature. Often after the administration of this remedy the temperature rapidly falls and the pain disappears, and rapid convalescence may follow. At other times, although the pain and fever are lessened, the inflammation of the joints persists. This is because there still remains in the blood a certain amount of nitrogenous material, which is one of the causes of rheumatism, and which should be eliminated. As these products of retrograde tissue-waste are only eliminated in combination with alkalies, as urates of sodium and potassium, these alkalies should be administered. My own plan is to always use the alkalies in addition to the salicylate of sodium until the urine becomes alkaline. When this occurs I diminish the amount of alkali, but still continue it in sufficient quantity to keep the urine alkaline.

When pericarditis occurs in the course of Bright's disease, treatment will not be of much service, but the usual regimen for Bright's disease will be proper.

As I believe that this is merely a simple inflammation of the serous sac, I shall treat it as we ordinarily do inflammation of a serous membrane. I shall apply blisters, and use acetate and iodide of potassium internally. This is not the alkaline treatment, for I do not push these remedies in large doses. We now are administering ten grains of acetate of potassium with five grains of the iodide four times a day. Small blisters are applied over the præcordia. The action of the heart has been supported by small doses of digitalis. On admission, the pulse was dicrotic, and the action of the heart embarrassed and diminished by the exudation around the organ. The indication was therefore to support the action of the heart while trying to remove the inflammatory exudate. We have given ten drops of the tincture of digitalis three times a day, and for the first day or two alcoholic stimulus was also used, but this has been discontinued.

I wish to make a few remarks on one symptom, to which I have intentionally refrained from referring until the present time. This symptom is friction-râle, which is very characteristic of pericarditis. So far as this case is concerned, this sign has been of no value in the diagnosis, because the case came under observation

after the friction-sounds had disappeared. When, however, friction-sounds are present, how will you differentiate them from a murmur produced within the heart? By the following points. A pericardial friction-sound is superficial; it is a grazing, to-and-fro sound. Sometimes pericardial râle cannot be distinguished from an endocardial murmur by these signs. The great point is that an endocardial murmur will be transmitted in the direction of the blood-current by which it is produced. In other words, if an endocardial murmur is produced in the aortic region, it will be transmitted into the carotid arteries or along the course of the aorta. If you have a mitral regurgitant murmur, it will be transmitted in the direction of the blood-current,—viz., back into the lung through the left auriculo-ventricular opening,—and may therefore be heard in the axilla. A pericardial friction-sound is, on the other hand, heard only at the position where it is produced, or in that immediate vicinity, and a pericardial friction-sound will change its position. If some of the exuded lymph is polished down by the action of the heart, the friction-sound will disappear from that position and will be heard at another point, at which new roughnesses form. An endocardial murmur does not change its position, and is constantly heard at the valvular points. The friction-sound is synchronous with the movement rather than the sounds of the heart. Commonly, it is heard over the base of the heart or near the orifices of the vessels. Change of posture may induce an increase of murmur, rendering a murmur which is faint in the vertical quite distinct in the recumbent. Finally, the alterations common to the walls of the heart in endocardial disease are absent.

THE TREATMENT OF PLEURISY.

I bring before you another case, which you have seen on a previous occasion. The patient came into the hospital about six weeks ago. He then had a large pleural effusion filling the left chest from the clavicle to the base. This effusion had taken place slowly, requiring at least ten days to reach its height, so that the patient did not suffer markedly from dyspnœa.

I have brought the case before you in order to show you two things: first, the progress of the case under treatment; secondly, to demonstrate the physical signs of pleural effusion in the stage of absorption. The patient was treated by jaborandi sweatings. The treatment has been a teaspoonful of the fluid extract of jaborandi every other day for two weeks, and then about three times a week to the present time; so that he has been under this treatment for four or five weeks. Together with this he has received ten grains of iodide of potassium three times a day. Within the last two weeks we have practised inunctions of mercurial ointment, applying it first to one axilla, then to the opposite axilla, and then to the groins. I have found that when a pleural effusion reaches a certain point absorption is very slow, and I believe that the careful use of mercurial ointment will quicken absorption in this stage.

I shall now percuss the chest, in order that you may see the improvement. While sitting up there is perfect resonance anteriorly. Over the back the percussion-note is almost flat. As you can see, small blisters, about the size of a dollar, have been applied. Often there will be, during the absorption of pleural effusion, a tympanitic resonance over the anterior portion of the chest. When these physical signs are limited to a small area near the apex of a lung, they may suggest the presence of a cavity. The mistake may be avoided by noting the absence of the usual auscultatory signs of such a condition.

The only further point which time permits me to observe is that the decubitus of the patient has a great deal to do with the shape of the effusion in the chest. This patient's chest still has considerable fluid in it. There is complete absence of respiratory murmur on the left side posteriorly. The reason that the remainder of the exudate occupies this position is because the recumbent posture has been maintained through the attack. I have instructed him to sit up more or less, and if he do this the absorption of the fluid will, I think, be materially quickened.

OXALURIA.—Dr. Charles N. Durselen, of Chicago, recommends the employment of biphosphate of sodium and nitro-muriatic acid in the treatment of oxaluria, the latter agent being especially applicable to cases connected with dyspepsia or disordered state of the liver, and in hypochondriacal cases. In simple cases, especially if accompanied by anæmia or with costiveness, better results will be obtained from the former remedy.

ORIGINAL COMMUNICATIONS.

ON RAPID DILATATION OF THE UTERINE CANAL.

BY WILLIAM GOODELL, M.D.

(Remarks made at the Obstetrical Society of Philadelphia, October 2, 1884.)

FOR many years I enlarged or straightened the uterine canal, according to the requirements of the case, either by tents or by Sims's operation, and preferably by the former. Having had several serious warnings, in the shape of inflammation following these operations, I began to perform them with fear and trembling. Yet nothing very untoward happened until the year 1878, when two grievous mishaps befell me.

A charming young lady, the centre of a large circle of admiring friends, came from a neighboring State to consult me about a dysmenorrhœa which grew worse and worse every year. The cervix was so bent forward, and the stenosis of its canal, *per se* as well as by angulation, was so marked, that I unhesitatingly performed Sims's operation. Within a few days septicæmia set in, soon the parotid glands swelled up, and on the ninth day she died. True it is that at the same time two piles also were tied; but this latter operation I had performed so many times with impunity that I was, and am still, disposed to attribute the blood-poisoning to traumatism of the cervix, and not to that of the rectum.

Hardly had I time to recover from this bitter blow, when a case of exhausting menorrhagia fell into my hands. The lady was the young bride of a husband well advanced in life, who doted on her as only old men dote on much younger wives. I dilated the cervical canal with tents and curetted many vegetations from the endometrium. A furious peritonitis set in, and in less than three days this young wife lay dead, and the husband was frantic with grief.

The anguish which I felt at the death of these two ladies, and the heart-rending scenes which I witnessed at their bedside, —scenes which I cannot now recall without emotion,—urged me to try any remedy that gave promise of efficiency combined with greater safety. In the search for a substitute I tried rapid dilatation, which Ellinger and others had proposed, and since that year—that *annus iræ*—I have not once performed Sims's operation for dysmenorrhœa, and I have so narrowed the field for the use of tents that I now very rarely resort to them. In short, rapid dilatation has proved, in my hands, so safe and so efficient an operation that I wish to urge its claims before this Society.

The instruments which I would recommend are two Ellinger dilators of different sizes. These are the best, on account of the parallel action of their blades. The smaller of these dilators has slender blades, and it pilots the way for the other, which is more powerful and with blades that do not feather. I have had the beak of this dilator changed from an obtuse angle to a slight curve, so that it can be reversed within the womb. The lighter instrument needs only a ratchet in the handles, but the stronger one should have a screw with which to bring the handles together. Lest the beak should hit the fundus uteri and seriously injure it when the instrument is opened, the blades are made no longer than two inches, and are armed with a shoulder which prevents further penetration. The larger instrument opens to an outside width of one and a half inches, and it has a graduated arc in the handles by which the divergence of the blades can be read off. The instruments which I now exhibit to you, and which I can recommend highly, have been made under my supervision by Messrs. J. H. Gemrig & Son, of this city.

In a case of dysmenorrhœa or of sterility from flexion or from stenosis, my mode of performing the operation of rapid dilatation is as follows. The patient is thoroughly anæsthetized, and a suppository containing one grain of the aqueous extract of opium is slipped into the rectum. She is then placed on her back and drawn to the edge of the bed, the knees being supported by her nurse. The light must be good, so that the operator may clearly see what he is about. By the aid of a strong tenaculum, applied through my bivalve speculum, the cervix is steadied and the smaller dilator is introduced as far as it will go. Upon gently stretching open that portion of the canal which it occupies, the stricture above so yields that when the instrument is closed it can be made to pass up higher. Thus, by repetitions of this manœuvre, little by little, in a few minutes' time a cervical canal is

tunnelled out which before could not admit the finest probe. Should the os externum be a mere pin-hole or be too small to admit the beak of the dilator, it is enlarged by the closed blades of a straight pair of scissors, which are introduced with a boring motion. As soon as the cavity of the womb is gained, the handles are brought together. The small dilator being now withdrawn, the larger one is introduced, and the handles are then slowly screwed together. If the flexion be very marked, this instrument, after being withdrawn, should be reintroduced with its curve reversed to that of the flexion, and the final dilatation then made. But in doing this the operator must take good care not to rotate the womb on its axis, and not to mistake the twist for a reversal of flexion. The ether is now withheld and the dilator kept *in situ* until the patient begins to flinch, when the instrument is closed and removed. A few drops of blood trickle out of the os. Occasionally a slight flow of blood will last for several days after the operation, simulating the menstrual flux. Often this flux is precipitated, or renewed, if the operation follows or precedes it too soon. The best time for dilatation is therefore midway between two monthly periods.

When compared with the cutting operation, this one looks like rough usage; yet the woman rarely needs more than two or three suppositories, and complains merely of soreness for one or two days. To forestall any tendency to metritis, she is kept in bed until all tenderness has disappeared. Pain is met by rectal suppositories of opium and by large poultices laid over the abdomen. I have seen slight pelvic disturbance arise from this operation, but it has always been readily controlled, and has not given alarm.

In the great majority of cases I dilate the canal not to the fullest capacity of the instrument, but to one and a quarter inches. Sometimes in an infantile cervix, which does not readily yield and might give way, the handles are not screwed down more than three-quarters of an inch or an inch. Tearing of the cervix has happened in two of my cases, from the slipping out of the instrument. In one, that of a virgin, the cervix was split halfway down to the vaginal junction. The other case was that of a multipara, whose uterine canal had been nearly closed up by applications of silver nitrate made by her physician with the view of curing what he supposed was an "ulceration of the os," but which was a bilateral laceration. The tissues, rendered cicatricial and brittle by the caustic, were torn by the dilator for about half an inch on the right side also. Here the hemorrhage was free enough to need styptic applications and a tampon. I could have stopped it by wire sutures, but this was not done, as it would have defeated the object of the operation.

For slight dilatations, such as for the office treatment of anteflexions and of stenosis, or for the introduction of the curette, or of the applicator armed with cotton, the more delicate instrument is quite strong enough, and an anæsthetic is not needed. Sometimes in a very sharply-anteflexed womb the dilator cannot be made to pass the os internum. This difficulty is overcome by first passing in a surgeon's probe, and then, along it as a guide, the dilator.

After a forcible dilatation under ether, the cervical canal rarely returns to its previously angular or contracted condition. Since lateral extension of elastic bodies antagonizes their length, the cervix shortens and widens, and the plasma provisionally thrown out by the submucous lesions sustained by the dilated part serves still further to thicken and stiffen its tissues. In other words, the stem-like neck of the pear-shaped womb is shortened, widened, strengthened, and straightened. Hence, for straightening out anteflexed or congenitally-retroflexed wombs, and for dilating and shortening the canal in cases of sterility or dysmenorrhœa arising from stenosis or from a conical cervix, the dilator will be found a most efficient instrument. In its results it is not infallible; I have twice been obliged to repeat the operation, and would like to have done so in several other cases had the women permitted it. In a very few instances I have been forced, as a final resort, to nick a pin-hole os externum; but I had not then learned how far I could safely stretch open the uterine canal, and the operation of dilatation was not so efficiently performed by me as it is now through a larger and riper experience.

But it is not to cases of dysmenorrhœa that I limit the operation of rapid dilatation. As stated before, I use it to stretch open the canal for the admission of the

curette and of sponge-tents, or for the purpose of making applications to the uterine cavity. In cases needing the irrigation of the uterine cavity I first dilate the canal with this instrument and introduce the nozzle of the syringe between the separated blades. This gives a free avenue for the escape of the liquid, and robs of its dangers this form of intra-uterine medication. I also resort to the dilator in order to explore the womb with the finger. For instance, in any given case of menorrhagia in which a polypus or some other uterine growth is suspected, instead of using tents, I put the woman under an anæsthetic, and, after the rapid dilatation of the cervical canal to the utmost capacity of the instrument,—viz., one and a half inches,—am enabled to pass my finger up to the fundus. This is accomplished either by drawing down and steadying the womb by a volsella forceps, or in thin subjects by forcing the womb down upon the finger through supra-pubic pressure on its fundus. In this way I have, over and over again, at one sitting discovered a uterine growth, twisted it off, and removed it. Usually in these cases I experience more difficulty in removing the polypus or other growth through the small canal than in twisting it off from its uterine attachment. It often has to be wire-drawn before it can be removed, and sometimes the os uteri has needed a few nicks. Usually when the menorrhagia is free the cervical tissue is so lax that there is no difficulty in the introduction of the index-finger up to the fundus, but sometimes only its tip can be made to pass the os internum. Yet even this limited degree of penetration is commonly quite enough to decide the presence of an inside growth. If it be not enough, I invariably search for a growth with a small pair of fenestrated forceps, and I have repeatedly seized and removed one the existence of which was merely suspected. After such operations the uterine cavity is thoroughly washed out with a solution of carbolic acid or of potassium permanganate.

I am sorry to say that I have not kept full records of all my cases of rapid dilatation. For instance, I have never recorded those office cases of dilatation in which ether was not given. Nor has any note been made of cases in which dilatation was performed under ether for curetting, for digital exploration of the endometrium, or for the removal of uterine growths. I have tabulated merely cases of dysmenorrhœa in single or in married women. In the married, with but three exceptions, which will be noted, painful menstruation was associated with sterility.

Including all the cases of dilatation performed under ether, I must have had over three hundred. I have limited myself to these cases because the use of an anæsthetic implies full dilatation,—one in which serious injury, if ever, would most likely be sustained. Yet there has not been a death, or a case even of serious inflammation, in my practice, and the results have been most satisfactory,—far more so than when the cutting operation was performed by me. The following are the statistics of my cases of dysmenorrhœa: single, 80; married, 88. Total, 168.

Of the unmarried, eighteen were unheard from after the operation, leaving sixty-two from which any data could be obtained. Of these, thirty-eight were cured, seventeen more or less improved, and seven not improved at all. Of these seven that were not benefited by the operation, five subsequently had their ovaries removed,—one of them by another physician and four by myself: of the latter, one died. In each one the ovaries had become so altered by cystic or by interstitial degeneration as to make the dysmenorrhœa otherwise incurable. Of the seventeen improved, there was one on whom öophorectomy was also performed; for, although the dysmenorrhœa was greatly relieved by dilatation, ovarian insanity and menorrhagia were not. The operation was a successful one, and my patient was not only cured of her hemorrhages, but she regained her reason. Out of these cases, the majority, although not wholly cured, were greatly improved. For example, one of them was formerly bedridden during the whole period of her menstrual flux, and had then to take large doses of morphia. She also suffered at those times from hæmatemesis and epistaxis. Since the operation she experiences pain for merely two hours, needs no anodyne, and has lost her ectopic hemorrhages. Her gain in health and flesh has been great. Another one, who was wholly crippled by her sufferings and made nervous by the dread of them, is now a busy nurse. For one hour at every period she

suffers a great deal; but she is too much afraid of taking ether to have a second dilatation performed.

Of those cured, two had Sims's operation performed previously without benefit, and were afterwards dilated; two were dilated twice before a cure could be brought about. The history of several cases merits more than a mere allusion. The sufferings of one of my patients at every monthly period had always been great, but while she was at a boarding-school they grew so intense as to cause furious delirium at those times. This finally developed into permanent insanity, with suicidal impulses. While in this condition she was placed in my hands. After rapid dilatation of the cervical canal, the dysmenorrhœa wholly disappeared. The exemption from pain toned down some of her more extravagant delusions, but she did not wholly regain her reason until a few months afterwards. She is now free from all menstrual pain, and in the complete possession of her mental faculties.

A Hebrew lady, whose health had suffered from dreadful dysmenorrhœa, was so much improved at one sitting that her physician and friends were amazed. Not long afterwards the doctor asked me to perform this operation upon another one of his patients, who was, if anything, worse. Her sufferings were so intense that he wrote, "I fear that another period might kill her," and urged an immediate operation. The cervix in this case was conical and very dense. Fearing a tearing of the parts, I screwed the instrument slowly up to one and a quarter inches, and kept up this amount of dilatation for some twenty minutes. The cervix sustained no injury. The canal has since remained patulous, and she is free from all menstrual pain.

Of the married, fifty-three were heard from. Of these, thirty-nine were cured, ten improved, and four unimproved. Out of these fifty-three cases, nine were not in a condition to conceive, three of them from fibroid tumors, two from destructive applications of nitrate of silver to a lacerated cervix, three from being over forty-one years of age, and one from being a widow. This leaves but forty-four capable of conception, and of these, eight, or a little over eighteen per cent., became pregnant. But the ratio is in fact larger, for several of my patients, fearing pregnancy, employed preventive measures after the operation. Then, again, I believe that others, who consulted me merely for painful menstruation, have not reported their subsequent pregnancies. For instance, two months ago I learned through the merest accident that the wife of a clergyman, whose cervical canal I dilated six years ago, has since been making up for lost time by giving birth to twins within a year after the operation, and later to several other children. She had been married eight years before she came to me, and had had her cervical canal dilated by tents and slit up with Peaslee's metrotome by a skilful surgeon. I have also had several cases of pregnancy following office-dilatations of the uterine canal, in which ether was not given, and consequently the lumen of the canal was not much enlarged. But such slight operations were not deemed worthy of record, and they therefore have no statistical value.

CLINICAL ASPECT OF SOME PERIPHERAL PALSIES.

BY LAMBERT OTT, M.D.,

Instructor in Nervous Diseases and Electro-Therapeutics in the Post-Graduate Course of the Jefferson Medical College.

IN glancing over the neurological literature of some of our recent and standard works on the practice of medicine, I find only a brief mention or an entire omission of some of the commoner forms of peripheral palsies, leading one to infer that they rarely occur or do not happen at all. Even some of those omitted I find to be very common, so that a short account of their clinical aspect will not be out of place. In degree of frequency the different parts of the body are affected in the following order: first the nerves of the face and neck, then the upper extremities, and lastly the lower extremities. I shall only mention some of those of the extremities.

Case I. Paralysis of Musculo-Spiral Nerve.—C. C., æt. 40 years, a book-canvasser, intemperate. Two weeks ago, after drinking heavily, he fell asleep with his arm resting over the back of a chair. In two hours he awakened, experienced nothing wrong, went home, and slept well that night. The next morning he noticed a numbness in the back of the forearm, and a tingling and numbness in the hand, extending along the dorsal surface of the fingers, with an inability to lift the hand. In a few days the tingling disappeared,

the loss of power in hand and numbness of dorsal aspect of thumb remaining.

Present Condition.—Has marked wrist-drop. By great effort he can lift his hand midway between flexion and extension. When the wrist is supported he can extend the two distal phalanges and adduct and abduct the fingers by the aid of the lumbricales and interossei. Supination and pronation are perfectly performed. He describes a numbness extending over the posterior interosseous space of forearm and dorsal aspect of thumb. Pressure over this space elicits tenderness. He can extend the last phalanx of thumb. When the wrist is supported he has normal grasp-power, and when unsupported he can grasp firmly only small objects. Flexion and extension of forearm are normal. No loss of sensation. Surface-temperature of extensor side of right (sound) forearm, 95°; left, 94°. After faradizing paralyzed muscles, surface-temperature, right 95°, left 95½°. There is slightly-diminished faradic contractility.

He was treated with counter-irritation over the course of the posterior interosseous nerve, and the labile descending galvanic current was applied to the nerve and muscles. He made a slow recovery.

This is a very common form of palsy, and presents many different degrees. It bears a great resemblance to the wrist-drop of lead-palsy, but is easily differentiated. The latter is generally bilateral, is usually accompanied with or preceded by symptoms of plumbism. Another differential point given by authors is that in paralysis of the musculo-spiral nerve you have loss of the power of supination, whereas in the paralysis of plumbism the supinator muscles are never involved. In reviewing my cases of musculo-spiral palsy, I find that this distinguishing point must be received with some allowance, as in all my cases of pure nerve-paralysis, even where the loss of power of extensor muscles was complete, supination was nearly normally performed.

When the nerve is injured high up, the triceps muscle is paralyzed. Then you may have, as in one case of mine (where the nerve was injured during the birth of the child), loss of power to extend the forearm and of supination of the hand. Erichsen, in his book on Concussion of the Spine, reports cases of paralysis of this nerve in fracture of the shaft, lower condyle, and lower epiphysis of humerus, in which the supinator muscles were not at all or but slightly impaired. Dr. S. W. Mitchell, in his "Injuries of Nerves," reports a case of injury to this nerve by the fragment of a shell, in which the extensor muscles of the thumb and fingers were completely paralyzed, whilst the actions of the supinators longus and brevis were but slightly impaired. In the same work he reports a case of injury to the median and ulnar nerves, in which the supinator longus muscle was paretic. The remaining muscles supplied by the musculo-spiral nerve were normal. There are various causes of paralysis of this nerve, the most fruitful being compression in intemperate men, where the arm is in some malposition whilst the muscular system is thoroughly relaxed by the intoxication.

Case II. Compression of the Median Nerve.—J. J., æt. 39 years, tailor. Had syphilis some five years ago. Is intemperate. July 5 he was drinking heavily, and fell asleep on his left arm. The next morning he noticed numbness in the left thumb, index, and middle fingers. He worked till July 11, when the numbness, and especially the weakness in the digits, mentioned, compelled him to cease. He has now, ten days after the accident, numbness of ends and palmar surfaces of thumb, index, middle and outer half of ring fingers, and of radial half of palm. There was also a space of numbness over the dorsal surfaces of the thumb and index-finger, involving in some way the radial distribution. Over the anæsthetic parts described he could not feel two points of the æsthesiometer ever so far apart. Compression over the course of the nerve elicited no tenderness. He could feebly flex, abduct, and adduct all the fingers, but the muscles having these functions were decidedly paretic, as the dynamometer registered 60 less as compared with the healthy side. The electrical condition was hyperexcitability to the galvanic current and slightly impaired faradic contractility. He was treated with rest to the parts, continuous current and counter-irritation over the course of the nerve. After four weeks of treatment he was markedly improved.

It is difficult to account for the anæsthetic surface on the dorsal aspect of the thumb, except by an interchange of sensory fibres between the median and radial nerves, or, as quoted by Alen,* W. O. Schnitzer infers from clinical data that the dorsal surfaces of some parts of the thumb, second, and third fingers have their cutaneous supply from the median nerve.

The median nerve, to the exclusion of

* Lähmungen der Armnerven, etc. Berlin, 1876. Abstract in Centralblatt für Med. Wissen., 1878, xvi. 190.

other nerves, is not so often affected with paralysis as the musculo-spiral; for it to be paralyzed in conjunction with other nerves coming from the brachial plexus is much more common. Generally the median and ulnar suffer together. Not uncommon causes of injury to this nerve are ill-adapted crutches, awkward venesections, rheumatism, etc.

Case III. Paresis of Ulnar Nerve.—K., æt. 80 years, watchmaker, a very healthy and vigorous old man. Has always worked with his right elbow resting on a table. In November he began to have symptoms of vesical catarrh, which undermined his health considerably. About this time he noticed a tingling and numbness in the distal ends of the little and ring fingers, and later his power of grasp became impaired. He was unable to hold his tools firmly in the hand. When I first saw him he had loss of sensation in palmar surface of little and inner half of ring finger, and in ulnar third of palm. The anæsthesia of the dorsal surface of hand was not sufficiently distinct to enable me to map out the ulnar distribution. His grasp was weak, the whole hand being affected, but the little finger and adduction of thumb to a greater degree. Pressure over the ulnar nerve elicited tenderness and a tingling in the ends of the inner two fingers. He abstained from work on account of the bladder-affection, to which I gave my whole attention. After this was removed and his general health had improved, his hand-weakness became prominent, but was soon relieved by counter-irritation, galvanism, and iodide of potassium internally.

This man had been leaning on his ulnar nerve probably for half a century, has never had a day's sickness in his life, and only when he is run down by a bladder-trouble did this paralysis manifest itself. Why it should take place just at this time can be explained in one of two ways. The previous ill health the man had been laboring under reduced the amount of areolar tissue, thus diminishing the natural protection and exposing the nerve to pressure, or his run-down system predisposed the nerve to disturbance from slight causes. Another fruitful cause is injury to the elbow-joint, as in a case of mine where there was a dislocation of the fore-arm backwards; after the reduction, the joint swelled, tingling and a drawing sensation appeared on the ulnar side of the hand and palm, followed by paralysis and atrophy of the muscles supplied by this nerve, which has not passed away to this day, four months after the accident. When paralysis of the ulnar nerve is complete, a peculiar deformity develops,—claw-hand,—which is due to the unopposed action of the antagonistic muscles of the interossei.

Case IV. Paralysis of the Peroneal Nerve from a Novel Way of Compression.—A. B., aged 30 years, pocketbook-maker. August 25, being out of work, he paved his yard with bricks, which required continual stooping. The third day he felt lame and sore from the extreme flexion of the knees, the left being the worst. He had great difficulty in rising from the stooping posture. A few days' rest restored the right leg entirely, the left continuing weak. He had at the time no fever, no muscular twitching, and no pain. Otherwise he was in the best of health.

Present Condition.—In walking, his left foot falls in extreme extension, and he lifts the foot by flexing the thigh, in order to prevent the toes striking the floor. He cannot flex, abduct, or adduct the foot, nor extend the toes,—movements produced by muscles supplied by the peroneal nerve. When any of these acts were attempted, there was involuntary extension of the foot. Sensation was lost on the outer aspect of leg, distinctly mapping out the sensory distribution of the peroneal nerve. Plantar reflex impaired, patellar reflex normal. Pressure over the nerve produced no pain. Electrical condition: both nerve and muscle show diminished faradic contractility. In the nerve the galvanic current gave Ca cc > An cc. The muscle, Ca cc = An cc. Surface-temperature (over anterior tibial group of muscles): left, 95°; right (sound) side, 97°.

He was treated by a labile descending galvanic current over nerve and muscles, rest, and potassium iodide internally. He did not improve after being under treatment three weeks, and left.

This paralysis was evidently due to compression of the nerve by the prolonged and extreme flexion of the knee-joint.

In support of my belief that this was the cause, I have the following experiment. Place an index-finger horizontally in each lateral half of the popliteal space; then stoop, bringing the entire weight of the body on the extremely flexed knee, and in trying to pull out the fingers you will find the outer fingers grasped more firmly: thus demonstrating that the outer lateral surfaces are brought in closer apposition than the inner.

Given a case of localized paralysis, by what points are we to distinguish whether it be central or peripheral?

PERIPHERAL PARALYSIS.	CENTRAL PARALYSIS.
Generally unilateral, and situated in the distribution of an individual nerve.	Usually bilateral when spinal, hemiplegic when cerebral.
Muscular atrophy.	No atrophy, unless multipolar ganglion-cells of anterior horns of gray matter are involved, and in those cases muscles are paralyzed which have different nervous supply, lying on opposite sides of the limb.
Paralysis first, and atrophy follows.	In progressive muscular atrophy there is also atrophy, but paralysis keeps pace with the atrophy.
Disturbances of sensation.	Seldom marked disturbance of sensation.
If of long standing, electro-muscular contractility absent, or the reactions of degeneration may be found.	Electro-muscular contractility only slightly impaired, except in infantile and adult spinal paralysis, where there is either lost electrical excitability or the reactions of degeneration; then the history of the case is a guide.

Paralysis due to compression or inflammation of the nerve presents important differences. In inflammation we have pain or elicit pain on pressure, which is seldom the case in paralysis due to pressure; and, if decided pain is found, we may conclude that there is more or less inflammation. Peripheral palsies are due to various forms of pressure, such as inflammatory products, cicatrices, callus, tumors, passage of fœtal head through pelvis, fæcal accumulations, muscular spasm, obstetric forceps, malposition of the extremities, and ill-fitting crutches. Where the pressure is temporary, at first both motion and sensation are affected, but the motor palsy lasts longer and is more profound.

The pathology of peripheral palsies has not been thoroughly investigated. S. W. Mitchell, after some experiments on nerves by compression where post-mortem examinations were made, states "that in all cases were noted some evidences of congestion, but the chief lesion lay in a very extensive disturbance of the contents of the nerve-tubes."

Prognosis is generally favorable. Where the cause has been only temporary and the paralysis partial or complete, it will require six to eight weeks to effect a cure. In cases of paralysis with atrophy, the prognosis is not so favorable as to a complete cure, but the palsy may be improved. The electrical condition of the muscles will give the best clue to base a prognosis upon. If there is no diminished electro-muscular excitability to either current, then the case is favorable. If the muscles do not respond to the faradic current, but to the interrupted galvanic, giving An cc > Ca cc, there is hope, after a long time of treatment, of restoring the parts to usefulness. When all electrical response is absent, the case is probably beyond a cure; but even then the interrupted galvanic current should be tried.

Treatment.—If the palsy be due to an acute or chronic neuritis, rest, soothing applications, and the ordinary antiphlogistic course should be ordered. In chronic neuritis nothing will yield more charming results than blisters over the course of the nerve. Iodide of potassium internally also acts well. Electricity should not be used in acute neuritis. Should the muscles respond to the faradic current, gently faradize three times weekly. If the muscles do not respond to this current, use the interrupted galvanic, placing that pole on the motor point of the muscle which obtains the minimum of contraction from the smallest number of cells. In compression-paralysis, if you find a spot of tenderness in the course of the nerve, use a blister. Otherwise nothing much can be done but to wait, keep up the tone of the muscles with electricity, and apply a constant descending current over the course of the nerve, in hopes of producing some healthy change in the nerve-structure itself.

FOREIGN BODY IN THE EYE CAUSING SYMPATHETIC OPHTHALMIA.

Read before the Philadelphia County Medical Society, September 17, 1884,

BY M. LANDESBERG, M.D.

I HAVE the honor to exhibit to you, Mr. President, to-night, one of the most interesting cases I have ever had the good luck to meet with in my practice.

This gentleman, 41 years of age, had

the misfortune of being struck by a splinter of metal in his left eye, July 13, 1881, about six weeks after he had come to this country. Blindness set in within ten minutes after the accident. He applied on the same day at Wills Eye Hospital, where he was advised to have the eye removed at once. Not quite relishing this prospect, he went to the Jefferson Medical College, where he was admitted for treatment after he had refused the enucleation, which was also at first proposed to him. There he remained for six weeks, during which time the incident inflammation passed off entirely. The globe was preserved, but vision was not restored. He enjoyed good health until March, 1882, when the first symptoms of sympathetic disorders began to develop in the right eye. Asthenopic troubles made their appearance, followed by sensitiveness to light and photopsies. The acuteness of vision gradually diminished as well for distant as near objects.

And now he began his wanderings from one oculist to the other: he hardly spared one, if I have to believe his testimony. Nothing was done for the benefit of the right eye, which changed from bad to worse. Enucleation of the left eyeball was pronounced by all authorities as the ultimate ratio by which the condition of "nervous irritation" in its fellow might possibly be checked.

When I saw the patient for the first time, September 5, 1883, I ascertained the following condition: No irritation whatever in either eye. Vision of the right eye was $\frac{1}{20}$; with convex 40, $\frac{1}{15}$. Pupil of normal shape, but of somewhat sluggish reaction; accommodation is impaired in consequence of paresis of the accommodative muscle. With naked eye, patient reads Jaeger 13 at about fifteen inches' distance; with the help of convex 10, Jaeger 3 at eight inches'. Field of vision and tension are normal. There exists an eccentric positive scotoma outside of the point of fixation. The subjective complaints are of photopsies and scintillations. Ophthalmoscopic examination reveals no morbid changes.

Left eye counts fingers at two feet peripherically outwards. The cornea shows a linear horizontal cicatrix on its lower third, running from the outer corneal margin towards the pupillary region. The lower half of the iris is disorganized, and presents in its middle a funnel-shaped depression, and close to its temporal border a mound-like elevation. The pupillary margin of this segment of the iris is connected by three blackish filaments with the dense opaque whitish membrane which stretches across the whole pupillary plane, filling up the latter to the greatest extent, even after the pupil had been dilated by a mydriatic.

The presence of the above-described "depression and elevation" in the lower half of the iris, which were situated just opposite the corneal scar, aroused my suspicion that the foreign body might possibly lie embedded in this region. An operation for the removal of the foreign body seemed to me to be a matter worth trying at first, by which nothing was risked and everything might be gained. The enucleation of the eyeball I regarded as the last expedient to which I would resort if I should be baffled in my intentions.

I spoke with the patient to this effect, telling him that I must have full liberty to act according to my best judgment, and to be allowed to enucleate the eyeball if I should fail to extract the foreign body.

He took time for deliberation and reflection until May 19, 1884, when he returned in the following condition. In the mean while he had repeated and completed his circuit among the specialists.

Vision of right eye, $\frac{1}{80}$; with convex 60, $\frac{1}{20}$; complete paralysis of the muscle of accommodation. With the naked eye he reads Jaeger 16 at eighteen inches' distance; with the help of convex 10, Jaeger 5 at ten inches'. The shape of the pupil is normal, its reaction sluggish. The visual field is somewhat limited in the upper sector, and its outer-upper quadrant is occupied to the greater extent by the eccentric positive scotoma. Patient sees all objects as through a veil, and is greatly annoyed by photopsies and scintillations, and by the perception of a bluish flame, which constantly occupies the centre of the visual field. He complains, besides, of the most various abnormal sensations in and around the globe, of a feeling of pressure in the depth of the orbit against the eyeball, of pains in temples and forehead, of sensitiveness to light, etc.

The ophthalmoscopic examination reveals venous hyperæmia of the retina. Optic disk is pinkish-red, of somewhat indistinct tints.

The condition of the left eye has not changed.

I operated upon the left eye in the following manner. I made a section at the sclero-corneal border, just within the limits of the morbid changes in the iris, introduced Liebreich's iris-forceps, grasped the whole segment of the iris which contained the "depression and elevation," drew it out and cut it off. No foreign body was found in the excised piece of iris. Now I again introduced a pair of forceps, caught the membrane, which covered the whole pupillary region, and managed to remove it entirely. On inspection, a small oblong piece of metal was found embedded in the posterior surface of the lower end of the membrane. Considerable hemorrhage followed the operation, and a few drops of vitreous escaped from the wound. A compressive bandage was applied on both eyes.

No reaction whatever followed the operation, and the healing process took place most favorably. The bandage was removed on the third day.

When I examined the patient on the eighth day, the condition was as follows: Vision of the right eye, $\frac{12}{15}$; with convex 72, $\frac{12}{12}$. Jaeger 12 is read at fourteen inches' distance with the naked eye. Subjective complaints greatly abated. No photophobia and lachrymation. Scotoma somewhat more transparent.

The left eye shows a very fine artificial pupil. The hemorrhage in the anterior chamber is only partly absorbed. Vitreous contains blood and dense floating opacities.

This remarkable improvement in the condition of the right eye had taken place without any other influences having been brought to bear upon it but the extraction of the foreign body. I abstained from all therapeutics during the eight days, and no more forcible proof of the sympathetic nature of the affection can be adduced than the spontaneous recovery after the cause of irritation had been removed.

An alterative and derivative treatment, which I now instituted, had the following effect. Vision of the right eye is at present $\frac{12}{8}$. The pupil is of normal reaction; the accommodative paralysis has greatly improved. His punctum proximum is at fifteen inches, and he reads, with the help of convex 10, the finest print (Jaeger 1) at six inches' distance. The visual field is normal, and the scotoma has contracted to an oblong rod of about two inches in length and of one-eighth inch in diameter. This scotoma is transparent, and does not interfere with vision. All subjective complaints and perceptions have vanished, with the only exception of the bluish flame, which, however, but faintly and only occasionally appears in the visual field. Background of the eye is normal.

Vision of the left eye is $\frac{1}{10}$, and may possibly improve still more in the future. There still are large floating opacities and some bloody streaks in the vitreous. The background of the eye can only dimly be seen. There are morbid changes in the retina and choroid, due to inflammatory processes which had taken place in these parts.

You have, gentlemen, before you a case in which a foreign body had penetrated into the eyeball, causing traumatic cataract and consequent morbid changes in the uveal tract and retina. The lens is absorbed, and a thick, opaque membrane (secondary cataract) obstructs the whole pupillary region. The foreign body remains embedded in the posterior surface of the lower end of this membrane for nine months, without doing any harm. Then the right eye begins to show symptoms of sympathetic trouble. Amblyopia and paralysis of the muscle of accommodation develop. And while these morbid changes of the most serious character take place, no inflammation proper, no objective irritation, can be observed in either eye. The injurious influences, which have continued to work for two years, are checked at once by the removal of the foreign body. The secondarily affected eye makes a marvellous recovery, which far surpassed all my hopes and expectations. Such a vision of $\frac{12}{8}$ is only met with in very rare instances; and the primary injured eye, which was not considered worth while being preserved, improves to such a degree as to enable the patient, should he have the misfortune to lose his right eye, to find his way in the streets, to recognize faces, to distinguish features, and eventually to gain a living by peddling, etc., if need should be. This case may justly be called a triumph of conservative surgery.

I take exception to the practice of all those surgeons who resort without further delay to enucleation in instances of injury to the eyeball with loss of vision. In

all cases in which there is no foreign body in the interior of the globe, we should abstain from operative interference and watch the eye with care. There is no danger in waiting. Sympathetic irritation is not likely to occur immediately after the injury. Enucleation itself is not so harmless as it is generally represented in text-books. It may sometimes give rise to sympathetic irritation, and I would impress this fact upon the general practitioner. It is not indifferent to the patient whether his blind eye be removed or not. A blind eye looks, in the greatest majority of cases, better than the artificial one, and we have to give to the patient the benefit, as long as it is compatible with the safety of the other eye. It is a matter of æsthetics. If a foreign body has penetrated the eyeball, the first indication is to remove it with an electro-magnet. If it cannot be found, and there is traumatic cataract, I would at once remove the latter: the body may be embedded in it. Should this removal fail, I advise enucleation at the same sitting. The foreign body extracted in this case was about three millimetres long, and of metal.

HYDROCHLORATE OF COCAINE IN AURAL AND OTHER CASES.

BY H. C. BOENNING, M.D.

ON November 3, 1884, I was requested to call on Dr. L. R. K. and remove a piece of cinder that had been embedded in the cornea. I found on examination that the cinder was firmly fixed in the cornea and surrounded by an area of discoloration. Efforts at extraction provoked intense suffering, and I determined to use cocaine to test its anæsthetic virtues. I obtained a weak solution from Dr. L. W. Fox, and dropped four drops every three minutes into the eye, using sixteen drops. In a few minutes the pupil dilated and the cornea was insensible. I removed the foreign body without causing the slightest pain. The cornea continued anæsthetized for nearly two days; the pupil remained dilated for a day longer, but gradually returned to the normal. Accommodation was not interfered with to any extent, J. No. 1 being read with the aid of the patient's ordinary glasses at ten inches. A curious symptom observed was a marked dryness of the throat and mouth, which passed off in the course of a day.

Since then I have used the cocaine in other eye cases. In a case of ulceration of the cornea accompanied with severe pain, the instillation of the cocaine was followed by a marked relief of all pain and a diminution of the attendant conjunctival injection. The photophobia present was not influenced by the cocaine; severe suffering was produced by exposure to light; but the constant pain attendant on the ulcer was relieved. The next day I tapped the anterior chamber, and the patient is now well.

About the middle of last month a child was brought to my office for ear-trouble. The history revealed an attack of scarlet fever two years ago, followed by deafness and a discharge from the meatus. An examination proved marked loss of hearing, but I could not determine anything more, the slightest contact with the ear producing pain and exciting the girl so much that the mother interfered. I ascertained that discharges of blood occurred from time to time, and that at first, when the child held her nose and mouth and expired, a hissing noise in the ear could be heard. I obtained the child's consent to an examination if it could be done painlessly, and forthwith used a strong solution of cocaine (eight-per-cent. solution), dropping about thirty drops of this into the ear in the course of half an hour, although much of the fluid overflowed the meatus. Ten minutes after the last drops were used I opened the meatus with a small bivalve ear-speculum and found it contracted by a growth—which partly filled the canal—of a pale-reddish color, bleeding slightly upon touch. The child (Mabel C. L.) felt the manipulation, but no pain was produced. Forcible expiration produced a hissing sound, and my diagnosis—vascular polypus with perforation of the membrana tympani and chronic catarrh—was confirmed. The next day the patient appeared for operation, and after using the cocaine again (although the parts were still numb) I removed the growth and washed out the ear, no pain of any consequence being caused. The case is progressing excellently, and I hope soon to close the perforation, which is near the lower portion of the membrane, being a circular hole with thickened edges.

My own child—a boy 26 months old—a week ago developed a small follicular abscess of the meatus auditorius, accompanied by pain, feverishness, and wakeful-

ness. I used the cocaine in his case twice in twenty-four hours with much relief. The next day I opened the abscess, which, of course, permanently relieved him.

November 5, Mr. Barcus, a student at medicine, kindly permitted me to drop some cocaine solution into his ear, the result being similar to the above cases. The canal was benumbed. A probe and speculum, which in the other ear caused pain when twisted or moved from side to side, was felt in the anæsthetized ear, but no pain was caused.

I would note, in no case were any unpleasant symptoms produced except in that of Dr. K., where dryness of throat was marked. This may, of course, have been a mere coincidence. In ear cases the solution should be much stronger than in eye cases, otherwise the effect will be neither so prompt nor so satisfactory.

528 Franklin Street.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY HOSPITAL.

SERVICE OF WM. PEPPER, M.D., LL.D.,

Provost of and Professor of Clinical Medicine in the University of Pennsylvania.

Reported by William H. Morrison, M.D.

CHRONIC INTESTINAL CATARRH.

GENTLEMEN,—I wish to again show you the man suffering with chronic diarrhœa whom you saw some time ago. He is now much improved. As you will remember, he has been suffering from a general catarrhal inflammation of the mucous membranes for at least eight years. There is probably in this patient a constitutional predisposing tendency to this affection; for without any unusual exposure he passed into this condition of catarrhal inflammation. Eight years ago, as a result of some little indiscretion, he began to suffer with dyspepsia. After three years he recovered from this attack, but was still subject to spells of dyspepsia on the least impropriety in eating. For the past two years he has been suffering with this irritation of the mucous membrane, chiefly of the larger bowel. When the irritation would subside, there would be atony, defective secretion, and constipation; then would follow colicky pain, griping, purging, and anorexia. This would pass away, and a state of constipation and torpor succeed. So it has been, up and down, for the past two years; but, on the whole, his course has been steadily downwards. The stools were liquid, and largely mixed with mucus. At times they would consist almost entirely of mucus, with but little fæcal matter.

The location of the pain, the considerable amount of mucus in the stools, the fact that gastric digestion was not much affected, and that there was not nearly as much prostration of the general health as we should have expected had the disease involved the higher portion of the alimentary canal,—all indicated that the disease was chiefly in the larger bowel.

In considering this case, I pointed out to you the great importance of rectal medication, and that in many instances the use of suppositories or enemata was the only way in which the disease could be cured; and that, under this plan of treatment, the recoveries were often remarkable, while the continued use of medicines by the mouth might prove ineffectual. By this plan the stomach can be reserved for the administration of tonic remedies.

In this case I ordered an injection of four ounces of water containing one grain of nitrate of silver and fifteen drops of deodorized laudanum to be thrown into the bowel, and the following to be administered by the mouth:

℞ Strychninæ sulph., gr. ⅓;
Acidi hydrochloric. dil., ʒij;
Tinct. gent. comp., q. s. ut ft. ʒiv. M.
Sig.—A teaspoonful before meals.

Under this treatment, decided improvement has taken place. The tongue looks better, and the diarrhœa is not so marked. The treatment will be continued. The restricted diet will still be insisted on, and the patient kept in bed most of the day, being allowed to be up a short time to take moderate exercise.

I have seen a number of remarkable results from even such simple injections as the one used in this case. A chronic dysentery is sometimes kept up by a trifling patch of inflammation in the rectum or sigmoid flexure. I have had a number of patients come to me who had been under treatment for years. They would have two or three loose stools in the morning, and then be comparatively comfortable all

through the day. Change of diet would have but little effect. There would be some colicky pain across the lower part of the abdomen and in the line of the large intestine, and not much about the umbilicus; the appetite pretty good, and the tongue clean, although rather pale. I have seen such cases which had existed many years, and in one of them the disease had lasted fifteen years, and had resisted all kinds of remedies. Thinking that there might be some inflammation of the lower bowel, I have ordered a few injections, and have had the patients return in a short time, stating that they had been cured by eight or ten injections of a simple character, so that it would scarcely seem credible that such long-standing trouble had been present. Of course, these are rare cases. There are, however, many cases of chronic diarrhœa which are beyond the influence of remedies administered by the mouth; and it is not until, by the use of medication addressed to the rectum, we have relieved some local catarrhal irritation, that we are able to effect a permanent cure.

Where the rectum is very irritable, and particularly where there are associated with it internal hemorrhoids, and possibly a disposition to looseness or diarrhœa, I wish to refer to the value of hot injections into the rectum, and especially such injections with the addition of some astringent. I know of no substance which is more agreeable as an enema than coffee. From half a pint to a quart of strong black coffee may be used, as hot as will be tolerated by the rectum. You have seen the beneficial effects of hot water in external inflammations in the form of hot-water dressings, in catarrh of the stomach in the form of hot drinks, and in uterine inflammation in the form of hot-water injections. In these cases of congestion and catarrh of the lower bowel, a good plan is to give in the morning an injection of hot water, and then at another period of the day, as at night, a second small medicated injection, and have the patient go to sleep and retain it.

On the other hand, I also want to call attention to the value of very small cold injections into the rectum in cases of irritable rectum. An injection of two ounces of water, as cold as the patient can bear without giving him a chill, retained all night, will sometimes act magically in relieving the irritation disposing to frequent discharges.

All of this simply goes to show the value of enemas adapted by your judgment to the different conditions of the system, and particularly the different local conditions: these constitute a valuable measure of controlling many conditions which too often are treated with medicines given only by the mouth, which never reach the spot.

IMPACTED CALCULUS.

This patient, a shoemaker, drank a great deal as a young man, and has drunk more lately. He has never had any venereal disease, but has been exposed a great deal; his habits have been irregular. Twelve years ago he had smallpox, and this was followed by rheumatism. Since then he thinks that his health has not been as good as before; but his dissipated habits may account for this.

Fifteen months ago he was much exposed to the wet, and, after about a week of general chilliness and discomfort, he began to have sharp darting pains over the crest of the left ilium, which grew worse and in a few days settled over the left kidney. The pains extended down the left groin, but not into the penis or testicle. There was also a constant desire to pass water, and the effort increased the pain. He got better, but still had soreness over the left kidney and along the crest of the ilium. Exercise and bad weather made this worse. At times he would have sharp spells of pain, and at such times would pass very little water. Four months ago he had another violent spell, and micturition became frequent and painful. Then he took a strong mixture of turpentine, and passed blood for several days. This acute attack subsided, and he returned to pretty much his usual state, except that he was more broken down. Before he came into the hospital, he had a similar attack, again took turpentine, and again had hemorrhage. On admission, there was pain over the left kidney, and darting and sticking pains ran around the crest of the left ilium. There was frequent micturition, but when the urine was examined it was found to be normal. The general health was run down. There was a distressing cough, and there was pain over the left lung. Physical examination revealed friction-sounds at the base of the left lung, and pericardial friction-sounds, a mitral

systolic murmur, and also a mitral presystolic murmur. There were evidences of pericardial adhesions in retraction of the tissues during systole. The lung did not advance over the heart during inspiration. There is a constant dull pain in the region of the left kidney and along the crest of the ilium, but there is no evidence in the urine of pyelitis. There have been several attacks of hæmaturia, and the blood seems to have come from the left kidney. This would suggest that there was a calculus in the left kidney; but there has been no continued evidence of inflammation of the pelvis of the kidney. Pyelitis reveals itself not only by pain, tenderness over the kidney, and attacks of lancinating pain in the line of the ureter, but also by changes in the urine, which throws down a considerable amount of pus, the supernatant liquid containing albumen rather in excess of the amount of pus present.

From the symptoms present, I am inclined to think that there is a calculus impacted in the substance of the kidney, and that attacks of congestion occur around it, which relieve themselves in the hæmaturia. As the stone has not gotten into the pelvis, pyelitis has not been established.

The progress of the case has not been satisfactory. He has been losing weight. Examining the lung, I find, at the left apex, impaired resonance and diminished fremitus, the vesicular murmur being absent. At the right apex there is marked resonance, and the respiration is rather puerile. There is a harsh systolic murmur over the apex, and friction-sounds are heard over the base of the heart.

The man, to-day, has a temperature of 102.5°. His tongue is clean, but rather glazed, and vividly red. Along its edges will be seen a number of pearly-white spots, which are very painful. These are minute aphthous ulcers, and, when they appear at a late stage of a chronic wasting disease, they are of bad omen. They are, however, not sufficient of themselves to justify an unfavorable prognosis; but in cases where you have been dreading deep-seated organic trouble, whether febrile or not, and you find aphthæ beginning to form in the mouth, it is of most unfavorable omen. In addition to the elevation of temperature, there is excited action of the heart, and the friction-sounds at the base of the heart are more marked than they were yesterday.

I cannot divest myself of the idea that this is a renewal of the disease at the base of the heart. There is considerable heaving and throbbing of the root of the aorta, and there are marked friction-sounds, and there is pain and tenderness on pressure being made over the base of the heart. There is, in all probability, a renewal of the disease at this point, which I regard as probably rheumatic in type. There is no evidence that the pulmonary disease is progressing.

I shall order a blister, three inches square, to be placed over the base of the heart, and shall give him the salicylate of sodium, in eight-grain doses, every three hours; and, by the rectum, twelve grains of cinchonidia, morning and evening. The efficiency of the salicylate of sodium will be increased by the addition of two drops of tincture of aconite to each dose.

TRANSLATIONS.

Treatment of Phthisis with Acetate of Lead.—Dr. Biedert, in the yearly report of the hospital at Hagenau, gives a number of cases of hæmoptysis which had been treated with acetate of lead. There were altogether ten cases, ranging in age from 15 to 46 years, suffering from severe and obstinate hemorrhages. The causes were phthisis in seven cases, chronic pneumonia in two, and acute pneumonia in one case. The drug, exhibited in doses of from 0.03 to 0.05 gramme every two or three hours, acted so promptly in arresting the hemorrhages that the author considers acetate of lead as the strongest and most satisfactory hæmostatic known. In seven of these cases the other usual remedies, such as ice, acids, alum, with narcotics and ergotin injections, had been used without result, and the hemorrhages had continued for considerable time before the acetate of lead was used. In three others the drug was given at once, and in all the cases the hemorrhages ceased in from twelve to thirty-six hours from the beginning of the treatment.

If the cough should be severe, the author advises combining the acetate of lead with opiates, and to continue the exhibition of the acetate of lead in gradually-diminishing doses for several weeks after the hem-

orrhages have ceased. A severe lead colic was not observed in any of the cases, but should such be the case the lead should, of course, at once be withdrawn. A like prompt action was observed in a case of obstinate renal hemorrhage in a child suffering from acute nephritis.

[This experience of the above observer is, however, not borne out in this country, since even larger doses of acetate of lead than those he mentions have failed to give as good results in checking hemorrhage as the usual combination of ergotin and opium. s.]

Non-Parasitic Chyluria and Chylous Hydrocele.—M. Le Dentu, at the Société de Chirurgie, recently read a paper on the filaria sanguinis hominis and the pathogenic *rôle* of this parasite in fatty hydrocele, in which, after reviewing the history of the discovery and defining its limits, he refers to another class of cases in which no parasite exists. He concludes as follows:

1. If it is demonstrated that parasitism is the real cause of a certain number of chylous effusions and of chyluria, without prejudice as far as other lesions are concerned, it appears certain that the parasitic theory is not applicable to all cases.

2. To this special cause should be added others, of which some are due to a general cause (peculiar alterations of the blood), some purely local in their origin (ruptures or compressions upon any point whatever of the lymphatic system).

3. Such compressions, whether affecting the thoracic duct or the principal lymphatic trunks, act as partial or total obstructions to the ganglia, and produce either a transudation or rupture, and, unless absorbed, an accumulation of lymph either in the tissues or in closed cavities.

4. It is by obstruction of the ganglia, of the trunks and their branches, that the filaria causes all the disorders attributed to it. Treatment of the parasitic form is therefore rendered unsatisfactory by the nature of the case.

Precautions to be Adopted in the Treatment of Phthisis.—At the International Congress of Hygiene held at La Haye in September last, the following conclusions were adopted regarding the treatment of phthisical patients, after an interesting discussion upon a report presented by Prof. Sormani, of Pavia.

"It is demonstrated that pulmonary phthisis can be, in certain cases, transmitted from the sick to individuals in health. Although the chances of this transmission are limited, prudence requires certain precautions.

"1. No one should be allowed to share the sleeping-chamber or the bed of a tubercular patient in an advanced stage of the disease. The apartment of a phthisical individual should be constantly aired and ventilated.

"2. The danger resides especially in the sputa, which should not be allowed to go on the floor or on clothing, where they may dry and become converted into dust.

"3. The sleeping-rooms, the bed-linen, and clothing which have been used by consumptives should always be disinfected. Steam (at 100° C.) and washing in boiling water are the best means of disinfection.

"4. Convalescents from chest-disorders and feeble and exhausted patients should especially avoid prolonged contact with the tuberculous."—*Revue de Thérapeutique Med.-Chir.*, No. 23.

Herpes Zoster and Facial Paralysis.—Dr. E. Voigt, in the *St. Petersburg Med. Wochenschrift*, relates at length an interesting case of acute herpes zoster (occipito-collosis) complicated with grave peripheral unilateral facial paralysis, and comes to the conclusion that herpes zoster is not necessarily dependent upon disease of the spinal ganglia, but, as in this case, may be caused by local neurosis of the sensory nerve-fibres. The case was treated by galvanism, with very good results as far as the pain and tinnitus aurium were concerned, but the facial paralysis was but little benefited. s.

Homatropin and Glaucoma.—In the *Centralblatt für Praktische Augenheilkunde*, September, 1884, is reported a case of incipient glaucoma produced by homatropin, occurring in the practice of Dr. Theodor Sachs, of Innspruck, in which eserine speedily brought about a return to the normal condition. This case is interesting from the fact that it seems to be the first one on record in which homatropin has produced glaucoma, and also on account of the prompt antidotal action of the eserine. s.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, JANUARY 10, 1885.

EDITORIAL.

1884—1885.

WHILE the annals of medical science during the last twelvemonth were not distinguished by any especially brilliant achievement or epoch-making discovery, yet it may be truly said that satisfactory and solid progress in rational medicine, conservative surgery, and the applications of sanitary science has undoubtedly been made by the profession as a whole. Within the limits of a brief article we cannot hope to do justice to the topic, but it may be interesting, as it certainly is timely, to cast a cursory glance over some of the prominent features characterizing the *annus medicus* through which we have just passed.

In the first place, upon calling the roll we miss many representative members of the American medical profession who responded *Adsum!* at the beginning of last year,—Samuel D. Gross, Willard Parker, J. Marion Sims, L. A. Dugas, S. M. Bemiss, J. G. Thomas, Lunsford P. Yandell, J. J. Woodward, Robert E. Rogers, Joel Foster, William Darling, Edward Jarvis; and, in Europe, Prof. Cohnheim, Reichert, von Zeissl, Balfour, Allen Thomson, Dumas, Wurtz, Tweedie, Radcliffe, Jäger, Sir Erasmus Wilson, Charles Clay, Frederic A. Mahomed. How the sad list extends! Death, who loves a shining mark, crowns the memories of 1884 with the myrtle rather than the laurel.

Turning to affairs of public health, we observe the increased interest in the meetings of the American Public Health Association, and as an indication of advance in such matters we may cite the formation of an American Society of Public Analysts during the past year. The existence of cholera in epidemic form in Italy, Spain, and France, and the prospect of an early outbreak in this country, have stimulated health-boards to increased activity, and suddenly inspired health-officers to new zeal in their work. The public interest in the subject finds expression in a bill now before Congress to re-establish a National Health Board, which has a fair prospect of passing, as it has been reported upon favorably in committee.

In surgery, the advance in knowledge of the results by operative interference in intra-peritoneal disorders has been decided. The carbolic spray is now rarely used, surgeons having learned that the peritoneum is far less vulnerable than was supposed, cleanliness, operative skill, and care in the after-treatment being the essentials. In this connection we must notice the operation recently performed by Dr. Sutton, of laparotomy and resection of the bowel for artificial anus, said to be the first operation of this kind performed in America. Cerebral surgery has also had a triumph in the localization by Dr. Hughes Bennett of a cerebral neoplasm under the dura mater, and its successful removal by Dr. Godlee in London. A passing reference only can be made to naso-pharyngeal surgery, but we cannot refrain from calling attention to the successful treatment of hay-fever by the removal of nasal hypertrophies, for which we are indebted particularly to Dr. J. O. Roe, of Rochester, and J. N. Mackenzie, of Baltimore.

The problem of the successful application of the electric light in a practicable form for diagnostic purposes seems to have been satisfactorily solved during the past year by the lamp of the S. S. White Manufacturing Company, which promises soon to be a part of the necessary armamentarium of the physician, as the companion to the speculum and laryngeal mirror.

In matters more directly medical there

is less to report. It can scarcely be said that the germ-theory has advanced greatly during the year. It is true that many new "germs" have been discovered, and attempts made to enlarge the list of zymotic disorders by the addition of many diseases, including eclampsia and alcoholism, but there has not yet been furnished the demonstration that microbes are the direct and sole causes of specific diseases. Nor can it be claimed that the recognition of these organisms—as, for instance, the bacillus of tuberculosis—has greatly aided our therapeutics: it might indeed be said that such therapeutic deductions as have been made from the germ-theory of disease have, in the main, failed to be endorsed by clinical experience. There has been a quiet but steady advance in general pathology during the year, which is probably most evident in diseases of the nervous system. A better prognosis is held for locomotor ataxia, and brain-lesions are more readily recognized and are treated with better chances of success than they were a year ago. Among the therapeutical advances we must include Da Costa's abortive treatment of erysipelas with hypodermic injections of pilocarpine, which has yielded striking results in his hands and promises to be a decided acquisition to practical medicine. The great event of the year was beyond doubt the introduction of the hydrochloride of cocaine into ophthalmic surgery by Koller, of Vienna, and its extension to other uses by a host of clinical observers who are enthusiastic in its praises. We might also speak of the introduction of antipyrin as a substitute for kairin as an antipyretic, but, as it is a preparation which has been kept secret, we think it advisable that the profession should exercise some caution in using it and in recommending its use. Etherization by the rectum had a very brief existence, and has now, we think deservedly, fallen into disrepute.

Among the most inviting problems for the pathologist during the coming year are the etiology of cancer and the unification of the different and conflicting views of tubercle, while the rational treatment of pulmonary consumption and cholera will continue prominently to engage the attention of the clinical investigator.

In beginning the new year, it is a subject of sincere congratulation to the profession throughout the entire country that the Code controversy has ceased to disturb the harmony of the New York medical societies, which now are free to continue their scientific work unhindered by ill-advised and ill-timed attempts to elevate the medical profession.

THE ABUSE OF ANTIPYRETICS.

BY physicians of sufficiently broad views to recognize "not only the disease in the sick man, but the sick man in the disease," the growing practice, which prevails more particularly in Germany, of administering enormous doses of antipyretics, is viewed with feelings of distrust, not unmingled with alarm. In a discussion at the French Academy, Professor Peter charged the advocates of the antiseptic or germicide treatment to be careful "lest in lifting a club to kill the germs they knock down the patient." Surely this warning was not given without sufficient cause. From the study of thermic fever, and of the effects of high bodily temperature upon animals, knowledge of unquestioned value has been derived, but from a hasty application of this knowledge to clinical medicine there has resulted an evident tendency to look upon fever as simply an excess of bodily heat, the object of treatment being mainly to restore the temperature to the normal; hence remedies capable of acting powerfully upon the nervous system, depressing calorification and assimilation, are largely used. That this view is so generally held is due largely

to the adoption of the views of Liebermeister.

Granted that hyperpyrexia adds an element of danger to the case, which sometimes makes it essential that the overheated blood and tissues should be relieved as rapidly as practicable, it does not follow that ordinary cases of fever require or will be benefited by toxic doses of quinine, salicin, salicylic acid, kairin, antipyrin, etc., which have been so highly vaunted. Professor Da Costa, in discussing the general management of fevers,* calls attention to the fact that it must not be inferred that massive doses of sulphate of quinia are to be employed in all the fevers of the continued type, and says that "such large doses cannot be given with impunity in various and dissimilar conditions; and it is very possible that while they reduce the temperature they may aggravate the disease or some of the lesions."

In a discussion upon this subject at the last meeting of the British Medical Association, Professor Gairdner† expressed a similar opinion, and, while not opposing the careful and judicious use of antipyretics, or of any other remedies, "he could by no means admit that the one object of treatment in an acute disease was to keep down the temperature by hook or by crook. It was impossible to regard the human body, in an acute disease, as a mere mass of overheated tissues, or to suppose that by merely cooling it down outside one could restore health and function when otherwise fatally disabled. When it was said that one must absolutely cool down the patient till it became necessary to give him stimulants to set him up again, he thought that the limits of safety in antipyretic practice had probably been exceeded. When it was said that, failing the cold bath, it was necessary to give enormous and repeated doses of quinine, and, failing these, enormous and certainly dangerous doses of digitalis, aconite, and even veratria, with the single object of getting down and keeping down the temperature, in diseases certainly admitting of fairly successful treatment without nearly so much interference, he confessed that he thought that the practice of medicine was running in a wrong direction, that they were likely to have the story of the past repeated once more,—a time of energetic and active practice (so called),—that is, of extremely powerful, and in some cases dangerous and even poisonous, remedies, so advocated as to make them appear indispensable, and to place them as such in the hands of every one all over the country." Feeling that such a custom was likely to run into abuse, Professor Gairdner entered a vigorous and timely protest against it, which may well be heeded by practitioners in this country.

It is noteworthy that at the last meeting of the Society of Physicians in Vienna Professor Nothnagel likewise called attention to the prevailing error of regarding fever as a disease *per se*, which is to be treated by any and every means that may influence it. He offers the pertinent suggestion that fever may often be a salutary process, and, in fact, is one of nature's regulative means. It is not evident that acute febrile diseases are shortened by simply diminishing bodily temperature, and therefore the routine or indiscriminate administration of antipyretics, based upon the single symptom of elevation of temperature, is unscientific and unsafe.

The Executive Committee of the American Public Health Association met in Washington, December 11, 1884, to make arrangements for the meeting in December. Subjects were selected for prize essays, and the Committee on Disinfectants was authorized to publish a preliminary report in view of the possible advent of cholera.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THE medical world here has recently been saddened by the death of one of our most promising young physicians,—Frederic Akbar Mahomed, of Guy's Hospital. Though only thirty-six years of age at his untimely death, Dr. Mahomed had for a number of years been a conspicuous figure in our ranks. Even as a student he won regard, no less from his general assiduity than by his work with the sphygmograph, then beginning to attract attention. He had not long been qualified when he was appointed resident medical officer to the London Fever Hospital. Here he worked hard at the matter of arterial tension, having the advantage of the supervision of Dr. Broadbent, Visiting Physician to the Hospital. To speak broadly, Dr. Mahomed found a rise of arterial tension to precede uræmia, especially in the kidney-complications of scarlet fever. Consequently he reasoned that if a brisk purgative were given to remedy the waste-laden condition of the blood, distinct uræmic symptoms might be averted. And practice proved the assumption to be correct. Since then, Dr. Mahomed's name has been closely linked with the subject of arterial tension, and much of our present knowledge of the significance of conditions of high tension is owing to his exertions. When he left the Fever Hospital he became Medical Tutor at St. Mary's Hospital, and after that Pathologist to the School. Here a sad incident occurred. He had to make an examination of a patient who had died of scarlet fever, and the result was that he took the infection home, where his wife lay just confined. She caught it and died, leaving him with two small children. Such a blow would have damped the energies of an ordinary man, but Dr. Mahomed never flinched from his duties, and worked indefatigably at his post. Soon an opportunity offered itself for his rejoining his old school,—Guy's. While Medical Registrar there, he saw it would further his end of gaining a place on the staff of that hospital to possess the M.B. of Cambridge. He had already supplemented his qualifications to practise by taking the M.D. of Brussels. He acted with his wonted energy. In order to qualify for his degree, he must reside so many terms at Cambridge. So Dr. Mahomed "went into residence" by taking his rooms and sleeping each night at Cambridge, while he continued his duties in the day as a Registrar at Guy's and an Assistant Physician at the Fever Hospital. And all this time he was earning his bread and maintaining his two little ones by teaching and writing. Such labors would have crushed most men; but Dr. Mahomed through it all presented the same erect carriage, the same elastic spirits, the same cheery demeanor, the same readiness to enter into any medical topic which might be exciting attention. And during all this time he was making valuable additions to our literature, his essay on "The Pre-Albuminuric Stage of Bright's Disease" having an especial interest at the present time, when our views on albuminuria are in a state of change. Dr. Mahomed attained his aim of becoming attached to the school of Guy's Hospital, where his diligence and his enthusiasm communicated itself to others. His teaching was sound and practical, while his belief in the efficacy of remedial agents was of the greatest service in a school where therapeutics were too little esteemed. Students found they could learn much from him, and Dr. Mahomed ever held his stores of knowledge at the disposal of his pupils. Liked, esteemed, looked up to as one who would occupy a commanding position, he was doing good work in his time and generation in his hospital and its school, and was also Physician to the Fever Hospital. Surely all this was work enough for one man. But Dr. Mahomed found time to be the moving spirit of the "Collective Investigation" movement of the British Medical Association, and was one of the Secretaries. The aim of the movement was to utilize the vast body of the Association by eliciting the opinions of its members on certain subjects, circulars being issued and widely circulated. The movement is thus far yet in its infancy, too much so to permit any positive opinion being formed of its usefulness or its comparative inutility, about which opinions differ widely. That something would have come of it if the man who more than any other was responsible for the movement had only lived to nurse his bantling is certain enough; but what may be its fate now is uncertain. In furtherance of his object, Dr. Mahomed went to the recent international meeting at Copenhagen, and set on foot an International Collective Investigation Committee. Shortly after this he took ill of enteric fever, how caught no one can say, and the attack was a severe one. Hemorrhages occurred and recurred, with the untoward result that the strong, courageous man lay still in death. The announcement of his death took many by surprise, for a man may be sick unto death in this large city, and few even of those who entertain warm friendly feelings for him know aught of it until there comes the startling rumor of his impending death, or more often the staggering announcement of his death in the obituary columns of our newspapers. The event is all the sadder that, with his wonted sanguine temperament, Dr. Mahomed had just moved into a large house, suitable to his position and prospects, in Manchester Square. Few men so young have been so universally regretted.

Not long ago, Dr. Broadbent was speaking of him as a remarkable man, not only for work in himself, but for his singular power of inspiring work in others. Prof. Humphry, of Cambridge, has borne his testimony in the *British Medical Journal* to the invaluable work he has done in the Collective Investigation movement. And, last week, one of those who were hostile critics of the movement steps forward at once to honor the man who set it on foot, and gives it as his opinion that the present is an opportunity for making a start in a new direction,—viz., out of the large and fast accumulating funds of the British Medical Association to grant to Dr. Mahomed's widow (he had married a second time) and children a yearly sum. The suggestion ought to meet with wide-spread adoption by the Association, for Dr. Mahomed had peculiar claims upon the Association, and every one who has its success at heart and would be glad to see it flourish in every way will be glad to see the suggestion carried out. Certainly, if ever its funds are to be utilized to grant pensions to the widows and children of those who have died in its service and wearing its harness, the present is a case in point. And, fortunately, Dr. Mahomed, with all his energies, made many friends and but few, if any, enemies, being singularly happy in the last in this jealous world.

Personally, I think some such recognition of what Dr. Mahomed did for the profession in general and the Association in particular is eminently desirable, and its rulers would do a graceful act if they granted a yearly sum to those who depended for their all upon a zealous worker well known to them.

Dr. Mahomed was a man of stalwart frame, tall and commanding in appearance, full of energy, who made his presence felt in any company. Those who were present at the Worcester meeting of the British Medical Association will not readily forget him when the meeting to discuss the compulsory notification of disease was falling into confusion and losing its way in propositions and counter-propositions. Dr. Mahomed, with his towering presence, his loud, ringing tones, and clear exposition, put all on the right track, and enabled the meeting to speak its mind and express its views, when, without him, in all probability, the meeting would have ended in "confusion worse confounded."

And now something may be said as to the practical aspects of one item of the life-work of this ardent student. His work with the sphygmograph led him to apply the instrument to the pulse in post-scarlatinal conditions, with the result that he discovered a rise in the arterial tension to precede the oncome of uræmic convulsions. This rise he attributed to the presence of excrementitious nitrogenized materials in the blood, not being efficiently cast out by the kidneys and accumulating in the blood. The well-known high arterial tension, the sustained pulse (full between the beats), with its characteristic square-headed tracing, of gouty conditions stood in a most suggestive relation to this pre-uræmic rise of tension in post-scarlatinal states. When uræmic symptoms are developed, it is the practice to act freely on the bowels, or nature spontaneously sets up diarrhœa, by which the defective action of the kidneys is vicariously supplemented and the uræmic condition relieved. The natural inference was that if such vicarious action were set up before the oncome of the uræmic state, it might be avoided, and such was the result in a sufficient number of cases to justify and corroborate the view. But behind the direct result of his acumen lay indirect results which did not escape Dr. Mahomed's vision. He made a study of Bright's disease, the correlative of the nephritic state left by scarlatina. Here also there is imperfect secretion of nitrogenized waste, accumulation of it in the blood, and sundry consequences of this, as serous inflammations and serous effusion into the brain. Excision of the kidneys of serpents is followed by a deposit of urates in the serous membranes, and in mammals extensive disease of the kidneys is commonly followed by morbid changes in the serous membranes. The rise in arterial tension in such cases is found to lead in time to hypertrophy of the left ventricle and accentuation of the aortic second sound. Not only are the semilunar valves closed violently, but on the arterial recoil the whole of the aortic root is violently distended, with the result very frequently of valvulitis being set up, followed by regurgitation through the injured valves. The distention of the arterial system leads to the development of atheroma throughout the arterial walls, and these hardened, brittle walls are liable to be cracked, with the formation of an aneurism, or maybe, if the rupture take place in the cerebral vessels, a blood-clot is formed, constituting apoplexy, or a stroke. Such association was observed as a matter of fact in the pathological room by Rokitansky long before the cause of the association, or *zusammenhang*, had been investigated. Then to these are added times when the accumulation of the azotized waste in the blood leads to acute uræmic evidences, or at other times to paroxysms of angina pectoris vaso-motoria. Angina is now known to be linked with vaso-motor disturbance; there is contraction of the arterioles, a damming of blood in the larger arteries, distention of the aorta, and, behind that, distention of the left ventricle. Sometimes the condition becomes so pronounced that the ventricle comes to a stand-still in diastole, unable to contract upon its contents, exhausted in its effort to overcome the resistance offered to the onward flow of the blood by the full state of the aorta. All these morbid states are the outcome of a waste-laden condition of blood.

Now, how is this primary condition to be met? Experience has told of the utility of cathartics. The rule of the older men, when they experienced a tight artery, was to bleed, if the condition was serious, and so to reduce the bulk of the blood, getting rid of so much waste matter with it. In less grave states the practice was to administer a blue pill and a black draught, and so "sweep out the liver," as they termed it. And very good practice this was in a great variety of obscure conditions, as John Abernethy found. It was not the use of such treatment which led to its abandonment; it was the abuse of it. When Abernethy encountered certain conditions of a somewhat confusing character, he recognized that a morbid state connected with the liver underlay them, and by the administration of a mercurial followed by a purgative distinct amendment was the result. Very commonly, dark, offensive motions, copious in bulk, were voided, and "inspissated bile" was a term then in common use. Such was Abernethy's practice, and his results, when published, led many others to follow his example. Ere long the blue pill and black draught were the fashion, and were resorted to in season and, what was worse, out of it. The wide-spread resort to such powerful medicaments led to much undesirable result. Doctors employed the heroic measure in unsuitable cases. Persons who suffered from "Liver" resorted to it habitually, and made it the excuse for a dietary far beyond their actual requirements, flying to the blue pill and black draught when "out of sorts," until a reaction set in and Abernethy's line of practice fell into disrepute. But, all the same, the pendulum is swinging back again; and now some of us at least know by experience the excellent effects of a mercurial followed by a purgative whenever the blood is surcharged with nitrogenized waste. And for this we do what the older men did,—viz., "feel the patient's pulse" first, and, finding it tense, take our measures accordingly.

Now, what Dr. Mahomed did was to give scientific precision to such observations. The sphygmograph writes down legibly and records what the trained finger feels, and so can convey a visible impression to others,—a matter of the highest value in teaching. When the student saw the sphygmograph-tracing before the eliminant treatment and after, he had a tangible proof of cause and effect. This is to him much clearer and more distinct than a careful interrogation of the patient's subjective sensations (a matter rather at a discount in medical teaching at the present day), and the tracing of high tension contrasted with the more normal tracing given by the artery after the blood had been cleansed.

Such, then, is a wider outcome of the research with which Dr. Mahomed's name will remain indissolubly connected. Of course he was not alone in the field, but his work stood on such a solid basis of individuality, and his observations were conducted on such a clear, unmistakable line, that his position was at once prominent and permanent. His loss to Guy's Hospital is great. It is not that Guy's has not on the list of its staff some admittedly able men; but it lacks that galaxy of talent which once shone over it and constituted it the finest school of medicine in England, certainly. Guy's has known evil times. The distinguished men who once gave it such prominence have passed away, and were not replaced,—from no fault of any one's, for Guy's never followed the rule which has worked so disastrously at some schools, of sending away its talent and then starving for want of it. Then it has suffered from civil strife, and been made the battle-ground of a fierce contest betwixt an arrogant sisterhood and the medical staff. It has its funds crippled by agricultural depression and political agitation in Ireland, where much of its property is located. Yet, with all this, it held its ground as the school whither the well-to-do general practitioner sent his son, if the youth hankered after his father's profession. But it has just lost Hilton Fagge, a man of weight on the teaching staff; and now a greater calamity has befallen it in the death of a man who not only held a conspicuous position in the great Borough school, but who had at an early age drawn the gaze of the medical world upon him by his actual achievements and the promise which lay in him. His profession regrets the loss it has suffered, and, beyond this general regret, there is that of those who enjoyed his personal friendship and who knew the sterling worth of the man. A movement is already on foot to secure some lasting memorial of him.

J. Milner Fothergill.

PROCEEDINGS OF SOCIETIES.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held December 24, 1884, John A. Wyeth, M.D., Chairman *pro tem.*

Dr. R. Van Santvoord presented specimens removed from three different patients. The first illustrated

DIPHTHERITIC CROUP.

The child from whom it had been obtained was 13 months old, an inmate of the Randall's Island Hospital. It had been suffering for about a month with diarrhœa, and was said to have had bronchitis. The house physician's attention had not been specially directed to the lungs until last night, when the nurse said the child had been ailing more than usual for some hours, and was in a somewhat stupid condition. The physician

found the patient breathing with difficulty, and examination of the throat revealed a patch on the right tonsil. Death occurred, as nearly as could be estimated, within twenty-four hours of the inception of the throat-trouble.

At the autopsy, membrane was found upon the right tonsil, epiglottis, larynx, and half-way down the trachea. The membrane was loose in the trachea. The trachea and bronchi were injected, and were coated with a copious secretion of muco-pus. About one-third of both lower lobes and about one-half of both upper lobes of the lungs were hepatized from catarrhal pneumonia. The solitary follicles in the intestines were enlarged.

PERICARDITIS, PLEURISY, PNEUMONIA.

The second case was that of a man who had entered the surgical wards of the hospital with varicose veins of the leg. About two weeks before his death he complained of pain over the pericardium, and shortness of breath, and afterwards manifested a certain amount of cyanosis. When Dr. Van Santvoord saw the patient, the heart was beating rapidly and forcibly, the apex-beat was in the nipple-line, but there were no auscultatory deviations, except that subcrepitant râles were heard over the lower lobes of both lungs behind. The patient was slightly cyanotic. Within forty-eight hours bronchial breathing was heard over the left lower lobe. Dr. Maxwell examined the heart several times, and found nothing abnormal other than that the area of dulness extended beyond the impulse of the apex, which was in the nipple-line. There were fine râles over the greater portion of the chest most of the time during the two weeks preceding death.

At the autopsy, the arachnoid membrane showed opacity; there was a certain amount of œdema of the membranes and excess of fluid in the cerebral cavities. More than a pint of fluid was found in the left pleura. The lower lobe of the left lung was compressed, the upper in a condition of gray hepatization, commencing to resolve, the entire lobe œdematous; the right upper lobe was in a condition of red hepatization, and the middle and lower portions in a less advanced stage of inflammation. The pericardium contained blood-stained fluid and had a coating of lymph. There was slight fatty degeneration of the cardiac walls; the left ventricular opening admitted three fingers, the right four. The spleen was shrunken; the kidneys showed a moderate amount of interstitial nephritis.

The case was chiefly interesting as illustrating how easily marked lesions might be overlooked by so competent a diagnostician as Dr. Maxwell.

BRONCHO-PNEUMONIA WITH PLEURISY.

The third specimen was removed from a child about a year old, in whose case no diagnosis had been made by the physician. It illustrated broncho-pneumonia and pleurisy of the right side.

PROLAPSUS OF THE RECTUM.

The fourth specimen was removed from the body of a child which died, aged 19 months, from broncho-pneumonia. The specimen showed prolapsus of the rectum, the peritoneum having also been dragged down to a very considerable extent with the gut. There had been diarrhœa.

Dr. J. C. Ripley asked Dr. Van Santvoord if he would relate to the Society what he had previously stated to him in connection with the first specimen.

Dr. Van Santvoord referred to a paper read at a recent meeting of the Academy of Medicine, in which the author, Dr. Winters, took the ground that laryngeal obstruction produced congestion of the lungs, with subsequent pneumonia. Dr. Ripley, on the other hand, claimed that when entrance of air into the lungs was partially obstructed in any portion of the tubular system of the air-passages, instead of having congestion we would have emphysema and consequent anæmia. Dr. Ripley's view was, the speaker said, the one which was accepted by pathologists generally. Dr. Van Santvoord thought that all who had examined the bodies of many children dead from obstruction to the air-passages must have found that emphysema was the usual condition present, and that broncho-pneumonia was exceptional. Consequently the idea of preventing the occurrence of broncho-pneumonia was not an indication for tracheotomy in laryngeal stenosis. He thought this fact was illustrated by the specimen presented, and said the condition of broncho-pneumonia which was present was antecedent to diphtheria.

Dr. Ripley did not wish to enter upon the discussion of this subject again at present, but would say that he had recently examined the lungs of a child which had died from croup after tracheotomy, and there was not the slightest indication of pneumonia; the lungs were anæmic and bulged out when the chest was opened.

TRACHEOTOMY FOR DIPHTHERITIC CROUP.

Dr. Chapin presented the trachea and lungs of a child, aged 3 years, and gave the following history. It had been ailing with a bronchitis for eight or ten days, when a diphtheritic membrane developed over both tonsils back of the soft palate, apparently extending up into the posterior nares. There was some hoarseness pertaining to the cough, and general bronchitis. Within forty-eight hours dyspnœa developed to an extent that caused considerable recession of the supra- and infra-clavicular and the supra-sternal regions. Within twenty-four hours more it was necessary to perform tracheotomy,—an operation which Dr. Chapin found far from being so

*

simple and easy to perform as some had recently claimed. Within three-quarters of an hour after the operation the temperature and pulse became considerably more elevated, but subsided again later. A large cast of the trachea was expelled, and the breathing became easy. The next morning the breathing again began to grow difficult, and in the afternoon was as labored as before tracheotomy had been performed. The tube, however, was perfectly clear, and it was evident that the stenosis was lower down in the respiratory tract. At about five o'clock, being called in great haste, as the child was apparently dying, he threw tripsin into the tube by means of the spray, and some pultaceous membrane was expelled, followed by easier respiration. After an hour the breathing was perfectly easy, and, the spray being kept up during the night, the child continued to breathe easily until death took place, the next morning, from blood-poisoning.

At the autopsy very thick membrane existed down to the tracheal wound. Below that point there were bits of membrane which evidently had been partially digested by the pancreatic extract; they extended down to the second division of the bronchial tubes. There were two spots of pneumonia at the bottom of the lower lobe of the right lung.

Dr. J. Lewis Smith remarked that in six or eight cases he had used extractum pancreatis mixed with the bicarbonate of sodium as an application to the faucial pseudo-membrane, and certainly in these cases the diphtheritic membrane had disappeared in a much shorter time than it had ordinarily in his practice. The question had once been raised as to whether we should not abstain from doing tracheotomy in cases apparently hopeless, as popular prejudice against the operation would be increased should the patient die. Dr. Smith would not hesitate to operate even if there were only a probability of relieving the child but for a short time.

Dr. Wyeth said, with regard to tracheotomy being a very simple operation, that the last time he performed it, which was for a foreign body in the air-passages, it proved very difficult. In that instance the trachea was not in the median line.

Dr. Ripley remarked that local applications in his experience seemed to have been failures. He once, however, poured lime-water into the tracheal wound by the teaspoonful, and the result was like that after the use of tripsin in Dr. Chapin's case: the membrane was dissolved, but the child died of diphtheria of the wound. With regard to the temperature running up after tracheotomy, that had also occurred in his practice, but, as a rule, unless the disease progressed, the temperature would fall the next day. Dr. Ripley further said that he thought the apprehension of harm coming from some fluid entering the trachea was unfounded. A teaspoonful of fluid entering the trachea would not reach the air-cells, and if it should, it would do no harm.

Dr. W. P. Northrup said that after the discussion on Dr. Winters's paper at the New York Academy of Medicine, he looked over the records at the New York Foundling Asylum, and found there had been autopsies in sixteen cases of diphtheria with marked laryngeal symptoms. In all these cases the membrane extended down to the finer bronchi, and in one case it extended to within a centimetre of the base of the lung. In reply to a question, Dr. Northrup said he believed there was pretty well marked pneumonia in at least four of the sixteen cases; also that tracheotomy was performed in about four of the cases; but Dr. Dwyre was in the habit of relieving the dyspnœa by a tube inserted between the vocal cords, so that in about twelve of the cases the laryngeal stenosis was entirely relieved.

Dr. A. Jacobi called attention to the fact that the pseudo-membrane in the bronchi and trachea was more likely to macerate than in any other locality. For this reason he believed there were many reports of success following the use of lime-water, alkaline waters, extractum pancreatis, etc. He further said children died from stenosis sometimes after tracheotomy, but not as frequently as when the operation was not performed. The stenosis, moreover, was of a different kind from laryngeal stenosis. It was true there was recession of the supra- and infra-clavicular and of the diaphragmatic regions, but not to the same degree as in laryngeal stenosis. Again, in laryngeal stenosis the respiration was long-drawn and slow, whereas in stenosis due to descent of the croupous membrane the respiration was shorter, more frequent, and resembling more the respirations in pneumonia and bronchitis. In a case presenting the latter form of respiration, the condition should not be regarded as one of pure and uncomplicated croup, but as one of croup with a mixture of inflammatory element, which was liable to cause death from pulmonary congestion, bronchitis, œdema, etc. This was a useful point in diagnosis and prognosis.

Dr. Ripley asked Dr. Jacobi if he wished to give the impression that in laryngeal stenosis the respirations were slow.

Dr. Jacobi said yes.

Dr. Ripley said he had records of a hundred cases in which the number of respirations per minute were noted, and they were invariably hurried. That was not only true in croup, but it was also true in asthma. The respirations, it was true, were a little different after tracheotomy had been performed and where there was secondary croup, but he thought it was not due to any inflammatory process, but in part to the obstruction being distributed more generally over the lungs,

and more particularly to the fact that the child by this time had become exhausted, the respirations were more shallow, and the dyspnœa was not so noticeable.

Dr. JACOBI thought the statement which he had made, based on observation of several hundred cases of croup, was also supported by theory. For example, a bottle capable of holding a certain amount of liquid would require a longer time to fill if the mouth were obstructed than if it were large and fully open. In laryngeal stenosis there would be no advantage for the child to voluntarily shut off one inspiration when the lungs were only partially filled with air and gasp for more breath. The obstruction to the ingress of the air would necessarily give rise to a longer inspiration to distend the lungs.

DIFFERENTIAL DIAGNOSIS BETWEEN PLEURISY WITH EFFUSION AND PNEUMONIC CONSOLIDATION IN CHILDREN.

Dr. J. LEWIS SMITH related the following history of a case, of which Dr. Northrup gave the result of the post-mortem examination. The child was 11 months old, and for two months had had pertussis, and for ten days preceding the 24th of the month, when he first saw the patient, had been suffering from increased bronchitis. In addition to this, Dr. Smith found, on the 24th, flat percussion-sound on the right side of the chest, except anteriorly, where dulness was not so great. His diagnosis was pleurisy, but, as the house-physician was unable to withdraw any fluid with the aspirator-needle, it seemed necessary to regard the case as one of the many in which it was difficult to differentiate between pleurisy and pneumonia in children. The physical signs, or signs obtained by auscultation and inspection, were often so nearly alike in pneumonia and pleurisy with effusion in children under fifteen months of age, that it was impossible to make a positive diagnosis. In the present instance there was no enlargement of the right side of the chest, nor bulging in the intercostal spaces. He noticed at one point on the right side a little vocal fremitus. The respiration was hurried, the pulse 180 to 190, the temperature 103.5°.

Dr. NORTHRUP said that at the autopsy he found the right lung much more than usually compressed and pushed forward. In the cavity of the pleura was a pint of greenish-yellow fluid, containing pus. Dr. Northrup said he supposed there was a record of seventy-five to a hundred cases of post-mortem examinations in the orphan asylum in which there had been an error of diagnosis between pneumonia and pleurisy in children.

Dr. JOHN A. WYETH presented four specimens illustrating surgery of the jaw.

SARCOMA OF THE INFERIOR MAXILLA.

The first specimen was of interest from a pathological point of view, being a portion of the lower jaw removed for sarcoma in a child 8 years of age. The portion removed extended from the second incisor to the last molar.

The second specimen illustrated the fact that operations performed early for ostitis of the lower jaw were less simple than if done later, after separation of the sequestrum. The third specimen had a history similar to the second, being likewise removed from the left lower jaw, the seat of necrosis.

The fourth specimen consisted of a portion of the left lower maxilla and dental nerve, which had been removed from a patient who had suffered for eleven years from tic douloureux of a severe type. After cutting down upon the nerve, he removed three-quarters of an inch of it and stretched the central portion. The patient had had no pain since the operation.

Dr. WYETH, in reply to a question by Dr. Jacobi, said the sarcoma in the first case had been developing, as he was told, for six or eight weeks.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, September 11, 1884.

The President, JAMES TYSON, M.D., in the chair.

DR. J. M. BARTON presented a specimen of *cystic papillary adenoma of the neck*, which he had removed from a patient at his clinic at Jefferson Medical College on September 6. The patient was a married woman, 31 years of age, the mother of three children. The tumor was of slow growth, having existed for five years, and having increased but little in the last two years. It gave no pain and but little deformity. It was about the size of a walnut, and lay beneath the clavicular extremity of the left sterno-cleido-mastoid muscle, in close proximity to both the subclavian and carotid arteries, from which it received a decided pulsation; on strongly pressing the tumor upwards and outwards, the pulsation ceased. The tumor was closely adherent to a number of large veins of new formation, which greatly increased the difficulties of its removal.

On section, it presents a number of alveoli, of variable diameter, communicating with each other and lined with a thick membrane, similar in appearance to the inner coats of the arteries. This membrane seems to have undergone calcareous degeneration in some portions. When the tumor was fresh, these cysts, on incision, were filled with a dark-red fluid like disintegrated blood.

Report of the Committee on Morbid Growths.—"A section made from the tumor of the neck presented by Dr. J. M. Barton shows a stroma of fibrous tissue, in which cavities are

seen, varying in size, lined with an epithelium having a cuboidal shape. From the margins of many of these cavities papillary ingrowths were noted, covered with cylindrical-shaped epithelium; other cavities are filled with the remains of cells or a structureless, colloid-like substance. The tumor may, therefore, be considered a cystic papillary adenoma, in which a colloid degeneration has occurred, or, from its location, it is not improbable that it may be either an outgrowth from, or a supernumerary, thyroid gland."

PHILADELPHIA NEUROLOGICAL SOCIETY.

THE regular stated meeting was held November 24, 1884, the President, Dr. S. WEIR MITCHELL, in the chair.

Dr. MITCHELL asked Dr. Woodnut, resident physician in the Philadelphia Orthopædic Hospital and Infirmary for Nervous Diseases, to read the notes of a case of erythromelalgia which had been under Dr. Mitchell's care in the hospital.

A CASE OF ERYTHROMELALGIA.

J. C. R., æt. 53, married, blacksmith, family history good. Mother died at 72; father still living. Six sisters still living and healthy; two died young. Has three children, all healthy. Has had scarlet fever, and at 20 variola, which left him slightly hard of hearing. Otherwise always perfectly well until September, 1881, when he first noticed pain on inner side of second toe of the left foot. One year after the third toe was affected, later the little, then the fourth, and about four months ago the great toe,—all on the same side. They were all affected in the same manner,—first a burning, then an aching, pain, and some weeks after there would be discoloration of more or less of the toe. Great toe has been least affected of left foot, only feeling sore at tarso-metatarsal joint.

One year ago the pain began in the right foot, first appearing, as in the left foot, in the second toe. Now it affects second, third, and fourth toes, but not so badly as in the other foot.

Pain is not noticeably worse in wet or cold weather. It is worse at night when the feet get warm. The last seven months, however, this was not so marked. Has occasionally had twitchings, chiefly at night, in calf of left leg and bottom of left foot. About six years ago the arms began to ache at night, and do occasionally yet. Pain is confined (to muscles apparently) just above the elbows. Arms are not quite so strong as formerly, but attributes it to want of use. Nine years ago ran a harrow-tooth in outer side of bottom of left foot. It healed without difficulty and left no apparent after-symptoms.

In January, 1883, had second toe of left foot amputated at proximal joint. It healed slowly, but relieved the pain not only in that toe, but also in the others.

The surgeon who removed the toe said that the amputated portion was "turned to gristle, and had no circulation."

Has no history of syphilis nor alcoholism.

At present all the toes affected are discolored. The left foot, up to the ankle, is covered irregularly with reddish patches, sometimes dark and sometimes brighter, disappearing on pressure, and more or less sensitive. Little discoloration on right foot except at corners of nails, and the disease has not developed so rapidly in the right as in the left foot.

Foot more or less swollen to the ankle. "Tendons seem sore." Occasionally pain in outer left ankle. Occasionally whole leg aches, but greater pain is on the spots of redness.

Pain, on walking, in the ankle and in the bottom of foot, so can only walk two or three blocks. Within the past few weeks a number of patches have appeared on the left leg, and one on the spine about the middle of dorsal region. For six or seven years has had occasional pains down the spine. It probably comes from a former sprain.

Also occasional sharp shooting pains at back of neck, on each side of spine, and down towards the shoulders, in the direction of brachial plexus. Not tender on pressure.

Sensation slightly diminished in the whole left limb, except on the patches of redness, where it is increased.

Elec. condition. No De R. Response equal in both legs to Galv. c. Far. c., slightly diminished action in left leg below knee. Sensation to both currents lessened in left limb. Measurement: r. calf, $13\frac{1}{8}$; l., $12\frac{1}{2}$; r. thigh, $20\frac{3}{4}$; l., $20\frac{1}{2}$.

Temp. R. $92\frac{3}{5}$, L. $93\frac{1}{5}$.

Dyn. R. 71, L. 70.

Appetite good, and, excepting pain, feels as well as ever. Urine, sp. g. 1.027; no albumen nor sugar.

His treatment has been absolute rest, massage, descending stabile galvanic current, and hot and cold applications to the spine once a day, chloride of gold and sodium. Fowler's solution and ergot have also been used.

11.21. An irregular-shaped patch appeared on dorsum of each wrist, preceded for forty-eight hours by pain and soreness; disappeared after being out thirty-six hours.

11.23. Redness appeared on each arm above elbow. Not preceded by pain, and appearing just after massage. Massage also brings it to view more plainly in the leg.

After the reading of the notes Dr. Mitchell brought the case before the Society.

Dr. CHARLES K. MILLS said he had seen quite a number of similar cases. His belief was that some at least of these cases were spinal in origin. The fact that some get well

is not against this theory. A few years ago he had attended a lady who had all the symptoms of diffused myelitis from unknown cause. He had also studied several cases of arsenical paralysis due to diffused myelitis. When the feet were pendent, in these cases, they would become hot, red in color, etc., like some of the cases of erythromelalgia. Dr. McBride, of New York, has described another type of cases, in which the limb is diminished in size, is cold, blue, etc.

Dr. MITCHELL said that he had no doubt that some of the cases of erythromelalgia were spinal in origin. He was not so certain, though, as to the spinal condition. In some of the cases an hysterical condition is present.

ON THE DIETETIC FACTOR IN THE TREATMENT OF ANGINA PECTORIS.* BY N. A. RANDOLPH, M.D.

There has recently been under my care a patient suffering from true angina, in whom, as is not seldom the case, any slight gastric irritation constituted the immediate exciting cause of the frequently-recurrent paroxysms.

After the last attack there existed an inability to retain the lightest and simplest foods, their ingestion inducing not only nausea, but much cardiac distress. Recourse was had, with advantage, to milk partially digested by the commercial Extractum Pancreatis, but the flavor of the resultant preparation was unappetizing, and finally became repulsive to the patient, who whimsically described its taste as that of "stewed corpse."

To meet this emergency there were devised two food-products, which I have not seen described, and which, in practice, proved eminently satisfactory.

I. *Pancreatized Oysters.*—The oysters of an ordinary stew (containing milk) are removed and finely minced, then returned to the liquid portion of the stew. The whole is brought to a temperature of 100° Fahr., the appropriate proportions of pancreatic extract and sodium bicarbonate are added, and the mixture maintained at the temperature mentioned for thirty minutes, with occasional stirring. It is then strained and served, and forms not only a highly nutritious and palatable soup, but one which is retained by very irritable stomachs, and utilized with a minimum of digestive power. After boiling, to prevent the further action of the digestive ferment, gelatin may be added, and the mixture served cold as a jelly. Cooked tomato, onion, celery, or other flavoring suited to the individual taste of the patient, may be added at the beginning of the artificial digestion, and the solid residue removed in the final process of straining, at which time it will be noticed that the minced oysters originally added have been in great part dissolved.

II. *Pancreatized Milk-Toast.*—Ordinary milk-toast, in which there is an abundance of milk, when digested in the manner just described becomes an almost homogeneous pulpy mass, which, when the crusts have been removed, is usually acceptably retained by the irritable stomach. In extreme cases, however, it may advantageously be strained and the fluid portion alone used, in which the partially-peptonized solution of casein of the milk is reinforced by actually-digested gluten and starch of the bread, together with a very little dextrin. Plain light sponge-cake may be similarly digested, and occasionally forms a desirable change.

In conclusion, I would express the hope that these rather homely suggestions may prove of value in other hands in extending the somewhat scanty bill of fare suited to patients suffering from gastric hyperæsthesia, and the various neurotic troubles of which such a condition may be the exciting cause.

Dr. G. BETTON MASSEY made a few remarks on

THE POLARITY OF CURRENTS OF MEDICAL COILS.

He called the attention of the Society to a singular omission made by the authors of most books on electro-therapeutics. After stating in the introductions that induced currents were to-and-fro, with constantly-changing polarity, they subsequently refer to these as having a fixed polarity, and make no explanation of this seeming impossibility. It is a fact readily tested by any one, that these coils furnish a current of one direction (the direct induced) at the opening of the battery circuit and none at the closure. As it is difficult to close the battery circuit by hand in these batteries without an irregular opening occurring at the same time, the currents due to this "raggedness" of the contact have been mistaken by some for inverse currents induced by the closure. Care, however, will eliminate this source of error, and prove that only currents produced in both primary and secondary coils at opening of the battery current are strong enough to be perceived by the senses. In the primary coil, whatever induction occurs at the closure, of course, goes through the cell as the short route. In the secondary coil this closure-current is supposed to be inhibited by the simultaneously-formed extra current of the primary coil. At any rate, it is not strong enough to be perceptible, and all currents therefore have a genuine polarity in our faradic batteries.

Dr. LLOYD said that he did not think that Dr. Massey was quite just in his criticism on modern writers, as Erb and one or two others mentioned the facts in their works.

Dr. MASSEY said he was misunderstood, as he had said that *most* writers did not allude to it.

TEMPERATURE RECORD OF EACH SIDE OF THE BODY IN A CASE OF HEMIPLEGIA.

Dr. W. SINKLER said he wished to call the

* Read at the October meeting.

attention of the Society to a temperature record which he observed in a case of hemiplegia. He said from the beginning to the end of the seizure the temperature on the affected side was from one-fifth to one degree higher than on the other side.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, THURSDAY, OCTOBER 2, 1884.

The President, R. A. CLEEMANN, M.D., in the chair.

DR. WILLIAM GOODELL read a paper on

RAPID DILATATION OF THE UTERINE CANAL.

(See page 265.)

Dr. HARRIS inquired about the danger of lighting up a former ovaritis by dilatation. The operation is successful, but that is its danger.

Dr. GOODELL said that he does not hesitate to operate, but always uses opium first, so that by the time the operation is over the patient is under its influence. He keeps them in bed and under the opium until tenderness has passed entirely away.

Dr. WILLIAM GOODELL exhibited a

DERMOID CYST OF THE RIGHT OVARY.

A saleswoman, aged 27, was obliged to give up her situation because she found herself unable to stand for any length of time. Her physician discovered a pelvic tumor, and called in Dr. Goodell to see her. The diagnosis was obscure, but he leaned to a fibroid degeneration of the right ovary. The woman was otherwise well, suffering no pain whatever, except when she was in the upright position. The operation was performed on September 8, and the tumor turned out to be a dermoid cyst. Being enveloped in the broad ligament, it was removed with difficulty. It is stuffed with hair and contained a plate of bone, the sharp edge of which was readily felt per vaginam; but it threw no light on the diagnosis, as it was mistaken for a fibroid spur. His patient did uniformly well, and is now out of bed. He stated that in his experience these tumors are very vulnerable, and often resent even so slight an operation as aspiration, inflammation and suppuration quickly setting in. A physician had to-day brought to his office a young woman who had been tapped last June with a trocar. Long hairs and much sebaceous matter escaped through the opening, which had not yet healed up, and it was for this reason that he had been consulted. Upon passing in a uterine sound, he struck a foreign body, which, from its density and the sharp click it gave, he was disposed to think was a tooth. He advised dilatation of the fistulous track and the removal of the offending body.

TWO CASES OF ÖOPHORECTOMY.

Dr. GOODELL also exhibited the ovaries which he had removed on September 17 and 29 from two patients, who now were doing well. He stated that the amount of tissue-change in these ovaries was very slight, and yet the suffering of each patient had been great. One had been an invalid for several years and bedridden for the past six months. She had lost much flesh, and was always groaning from left ovarian pain unless under the influence of large doses of morphia administered hypodermically. The left ovary was found to be undergoing cystic degeneration, but the right one was so sound that in its removal he was glad to have the backing of Prof. W. S. Playfair, of London, who was present at the operation. For he believed that in most cases needing öophorectomy the results usually showed failures unless both ovaries were removed and the menopause established. Convalescence after the operation had been retarded by great and painful swelling of both parotid glands, which developed without any marked rise in the temperature and without acceleration of pulse, and declined without suppuration,—behaving exactly like mumps. This made his third case of parotitis following the removal of the ovaries. Not one had ended fatally, and from the very slight febrile movement he thought that the complication was not symptomatic, as in blood-poisoning, but sympathetic, and that a strong kinship, recognized by laymen, existed between the sexual organs and the cervical glands. Since the operation all pelvic pain had ceased.

The other patient was a poor woman, aged 30, the mother of seven children. She was sent to him by Dr. George S. Hull, of Chambersburg, Pa. Three years ago she began to suffer from double ovaralgia. The pain never left her wholly, but it began to increase in severity a week before the period, culminated during the flux, and faded off afterwards. Large doses of anodynes were also needed in this case, and she was unable to work. The case was clearly one of ovarian dysmenorrhœa, and he believed that she would be permanently cured.

BACILLI IN SYPHILIS.—The discovery of bacilli in syphilitic lesions is announced by Dr. Lustgarten (*Wien. Med. Wochensch.*, No. 47). His researches, which were made in Weigert's laboratory at Leipsic, consisted in a special method of preparation and staining of sections of primary chancres and a gumma. In all were found, isolated or in small groups, slender, straight, or slightly-curved bacilli, much resembling tubercle-bacilli. The organisms were embedded within swollen lymphoid cells, and exhibited transparent spots, which resembled the "spores" of Koch's tubercle-bacillus.—*Lancet.*

REVIEWS AND BOOK NOTICES.

THE PHYSICIAN'S DAILY POCKET-RECORD. Comprising a Visiting-List, many useful Memoranda, Tables, etc., by S. W. BUTLER, M.D. Nineteenth year. New and thoroughly-revised stereotype edition, with Metric Posological Table, etc. Edited by D. G. BRINTON, M.D. Philadelphia, 1885. Patent flap.

This is a standard visiting-list, well known and generally liked by those who keep a pocket-record: it is substantially bound, with a self-acting clasp, contains good paper, and satisfactorily answers its purpose.

THE PHYSICIAN'S VISITING-LIST (LINDSAY & BLAKISTON'S) FOR 1885. Thirty-fourth year of publication. Philadelphia, P. Blakiston & Co.

Blakiston's Visiting-List for 1885, with the tuck-flap, is an old favorite with many members of the profession. It is a little smaller in size than the preceding, but contains the usual lists of new remedies, poisons and antidotes, and posological table, and is a good, practical pocket-record.

THE PHYSICIAN'S COMBINED DAY-BOOK AND LEDGER. By H. T. HANKS, M.D., New York. For sale by J. H. Vail & Co., New York. Half-Russia back and corners, and cloth sides. For 2200 accounts, $4.50; 3700 accounts, $5.50.

Those who do not use a pocket visiting-list will find in the Combined Day-Book and Ledger a system of book-keeping well worth examination. It is claimed that in its facilities for keeping the accounts legibly and correctly with the least possible expenditure of time and labor this method is superior to all others that have ever been devised. From careful examination, it appears that this system of book-keeping has many and decided advantages to commend it to the attention of the busy physician, who will find by its aid that the labor of keeping his accounts is reduced to a minimum.

HENKE'S ATLAS OF SURGICAL ANATOMY. A Series of Plates illustrating the Application of Anatomy to Medicine and Surgery. Translated and edited by W. A. ROTHACKER, M.D., Pathologist to the Cincinnati Hospital, Lecturer on Pathological Anatomy in Miami Medical College. Cincinnati, A. E. Wilde & Co., 1884. Bound in half-morocco, $10.

The translator and publishers have rendered a real service in placing in such accessible and acceptable form the well-known Topographical Anatomy of Henke: it is a clear, plain exposition of applied anatomy for everyday use. To the student, surgeon, and physician these plates are useful, showing the various organs and structures in their natural relations, thus refreshing the mind and reviving the lessons learned in the dissecting-room and operative surgery class.

There are eighty-one full-page plates, printed on heavy toned paper, with abundant explanatory references upon each diagram. For the most part the figures are well drawn and distinctly printed, and include representations of the principal organs of the body, seen *in situ* and in section. The value of this work is self-evident, and its execution deserves the highest commendation.

THE MEDICAL RECORD VISITING-LIST, OR PHYSICIAN'S DIARY FOR 1885. New York, William Wood & Co.

This is the *édition de luxe* of visiting-lists, having gilt edges, Russia binding, and large flap, and is probably the favorite for New-Year's gifts to physicians.

GLEANINGS FROM EXCHANGES.

GASTRITIS FAVOSA: A NEW DISEASE.—At the meeting of the Vienna Imperial and Royal Society of Physicians on the 28th of November, Prof. Kundrat exhibited specimens of a unique kind. The case was one of favus universalis which had given rise to an abscess of the thigh, and had terminated fatally from severe gastro-intestinal disorder marked by an uncontrollable diarrhœa. Numerous erosions mingled with diphtheritic swellings were found in the mucous membrane of the stomach, and the intestines contained some foul putrescent masses and much mucus. Prof. Kundrat at once declared the diphtheritic swellings to be due to the favus fungus,—a view which was confirmed on microscopic examination. This is the first recorded instance in which the mucorineæ have been the cause of death, as it is the first of favus of the stomach and intestines. Indeed, the naked-eye appearance of the tumors in the stomach closely resembled the favus cups on the skin, and the fact that but little of the fungus was found in the intestine was explained by Prof. Kaposi by their having undergone putrefaction in the bowel. The patient had previously been shown to the Society by Prof. Kaposi as a rare instance of favus, which covered the entire body, affecting even the finger-nails (attributed to his habit of scratching himself constantly). Favus of the stomach is as unknown a condition in animals as it is in man; at any rate, Prof. Csoker, of the Vienna Hospital for Animals, stated that it never occurred in cats, although these animals frequently eat rats infested with the fungus. Prof. Bamberger suggested that in this case the gastric mucosa was in an unhealthy condition at the time of infection, thereby affording a favorable nidus for the growth of

the fungus. It must be borne in mind that the mucorineæ, unlike the schizomycetes, can thrive in acid liquids, and may therefore grow with impunity in the stomach. The case is of great importance, as showing that, if they do gain access to the interior of the body, these fungi may be a source of danger and lead to a fatal result, thereby disproving the usually-accepted notion of their harmless character.—*Lancet.*

THALLIN.—The industry of Continental chemists in the application of the synthetical methods to the formation of new compounds has brought to light a new antipyretic agent, which appears to have been used successfully in a large number of cases in the clinic of Prof. Nothnagel. It has the constitution of a secondary chinoline base, being one of a number of chinoline derivatives prepared by Prof. Skraup, and is represented by the systemic name, "Tetrahydroparachinanisol." The salts of this base, which have an acid reaction, are freely soluble in water, and have the property of forming green compounds when treated with solution of ferric chloride and oxidizing agents. On account of this peculiarity, the cumbrous systemic name has been dropped in favor of the shorter designation, "thallin." The hydrochlorate, sulphate, and tartrate of thallin and the hydrochlorate of ethyl thallin are the salts that have been employed, and these are said to show great antipyretic activity in doses of quarter, half, and three-quarters of a gramme, —a point in which thallin would seem to compare favorably with some of its competitors. The lowering of the temperature is said to take place gradually and to last a considerable time, whilst it is not accompanied by any secondary disturbances. Thallin can be conveniently administered in wafers containing a quarter or half of a gramme of the sulphate. Two other chinoline derivatives have been experimented with; one of them has but slight antipyretic properties, whilst the other was fatal to guinea-pigs in doses of from .2 to .6 gramme, violent tetanic seizures being excited.—*Lancet.*

ALKALOIDS OF QUEBRACHO.—For a long period of time the inhabitants of South America have employed quebracho on account of its febrifuge, tonic, antiasthmatic, and astringent properties. White quebracho, of which three species are recognized, is a tree belonging to the family of Apocynæ, which abounds in the Argentine Republic. Penzoldt in 1879 proved that a decoction of the bark slowed the pulse and diminished the frequency of respiration, but he noted no antipyretic effects. Berthold and Picot confirmed these results. The value of one of the alkaloids, aspidospermine, discovered by Fraude, in relieving dyspnœa has been corroborated by a number of independent observers. Hesse has determined that there are as many as six alkaloids in the aspidospermine of commerce. MM. Eloy and Huchard have separated the alkaloids in a state of purity, and have made a series of thirty-six physiological experiments in reference to their antithermic action. The experiments were made on rabbits, guinea-pigs, and dogs, by means of subcutaneous injections. All the alkaloids were found to exercise a marked antipyretic action. A remarkable effect was also observed to occur in the color of the venous blood, which became of a vermilion-red tint like that seen after poisoning by prussic acid and carbon monoxide. Subcutaneous injections of from .10 to .20 centigramme of the hydrochlorate of aspidospermine, in patients suffering from typhoid fever, appeared to lower the temperature in cases where quinine had had no effect. Lactate of aspidospermatine is a more powerful alkaloid in reducing the temperature than hydrochlorate of aspidospermine; the sulphate of hypoquebrachine and the lactate of quebrachine are still weaker antipyretics.—*Lancet.*

THE ETIOLOGY OF TRICHORRHEXIS NODOSA.—In opposition to the opinion of Eichhorst, who has recently written upon this condition, Dr. Wolffburg states that the sole cause of trichorrhexis nodosa is the improper care of the hair. He showed in his own person that it could be produced in the beard on one side by rubbing it energetically and frequently, the other side meanwhile being normal. The following are the grounds upon which the author bases his belief in the mechanical causation of trichorrhexis (*Centralblatt für Klinische Medicin*, No. 38, 1884): 1. The anatomical appearances,—the hair, except for the nodules, is healthy. 2. The localization,—the affection has hitherto been observed only in the larger hairs of the beard, and especially in those so situated as to be most exposed to mechanical injury when the face is rubbed, as in the beard covering the lower jaw. 3. The explanations hitherto offered are insufficient. 4. The supposed incurability of the affection is easily explained when one remembers that the treatment usually recommended (frictions with alcoholic preparations or irritating salves) only furnished new sources of irritation to the ill-treated beard.—*Medical Record.*

THE CONTAGIOUSNESS OF INEBRIETY.—The climax of absurdity in regard to inebriety appears to have been reached. In a recent number of the *Alienist and Neurologist*, Dr. Crothers, assuming that inebriety is a disease, classifies it among contagious disorders, and ventures to illustrate his conclusion by the citation of cases, and pretends to trace its analogy to measles and other zymotics, but he omits to take note of the difference in their environments. — *Sanitarian.* [If this be true, what a field it opens for preventive inoculation!—ED. P. M. T.]

IRRITABLE SPINE AND SPINAL MYALGIA.—In a lecture (*The Practitioner*) upon this subject, Dr. S. J. Gee says that the disorder is a real one and not hysterical, although it may be associated with hysteria. Although the patient often exaggerates her symptoms, it cannot be regarded as imposture, because it is unintentional and has underlying it a genuine disorder. Irritable spine means simply painful spine, either neuralgic or myalgic. In regard to treatment, as the patients are generally poorly fed, it is necessary in the first place to see that they take food enough, that it is of good quality, and that it is given sufficiently often. A moderate allowance of alcohol in the form of stout, ale, or wine may be reckoned as part of the food. The muscles must be well nourished, or the treatment will do little good.

Secondly, the muscles must be rested. The pain is of the nature of fatigue. The muscles of the neck and back cannot be rested unless the spine be supported in its whole length; the patient must lie on a couch or recline in a very easy chair with a long, high back, and with elbows, so that the weight of the arms is taken off the spine. Yet here also is a difficulty. A prudent man thinks twice, or a dozen times, before he condemns a young woman to the sofa. There is danger that she will never rise from it, and will be a burden to herself and all her friends and relatives for the rest of her life. Beware of insisting too much upon the repose of the couch: it were sometimes far better that they should continue to complain of their pains. In this dilemma the best advice I can give you is that you should recommend a certain amount of reclining, and carefully watch lest your patient show signs of becoming a slave to the sloth of the sofa. With the better sort of women there is little fear of this: they prefer an irritable spine to laziness.

Another means of resting the muscles which perhaps occurs to you is well-fitting stays. But on second thoughts you will see that stays do not come high enough to support the head and shoulders; and it is here that spinal myalgia most commonly shows itself.

Local applications to the spine, more or less anodyne, are useful. Warmth, for instance. Our patient declared she was much relieved by a douche of hot water to the spine. Belladonna liniments are useful.

Lastly, I think that patients who have once developed an irritable spine seldom altogether lose it, or at least they will seldom confess that they are altogether free from pain in the back.

CONVULSIONS CAUSED BY CONSTIPATION.—Dr. J. F. Baldwin, in the *Columbus Medical Journal*, reports the case of a lady 67 years of age, though apparently much older, whom he found in a general convulsion. The eyes were turned up, the eyelids half open and twitching, the limbs jerking about and with a slight tendency to opisthotonus. On extending the arms at right angles to the body, they would remain rigid, as in catalepsy, except some fibrillary twitching, for some minutes, when they would gradually, and with increased twitching, sink to the sides. She was entirely unconscious, and could not be aroused. She had been in this condition for three hours. Two hours later, after several large doses of potassium bromide, she returned to consciousness, and said that she felt as well as usual. She had taken salts the night before, which had operated freely. The urine was normal. The next day her convulsions returned, and recurred daily for the next two weeks. A full dose of croton oil was administered, which operated freely. Antispasmodics, quinine, and purgatives failed to relieve her condition, and she was manifestly growing weaker. Upon making a digital examination, the uterus was found in good position, but an impaction of fæces as large as a child's head was discovered in the rectum, notwithstanding the purgatives had acted freely. The mass was removed, and the patient at once recovered.

MISCELLANY.

THE NINTH INTERNATIONAL MEDICAL CONGRESS, TO BE HELD IN WASHINGTON, D.C., IN 1887.—The Committee on Organization of the Ninth International Medical Congress met in Washington, D.C., on November 29, 1884, for organization.

The following rules were adopted:

1. The Congress will be composed of members of the regular medical profession who shall have inscribed their names on the register of the Congress and shall have taken out their tickets of admission. As regards foreign members, the above conditions are the only ones which it seems at present expedient to impose.

The American members of the Congress shall be appointed by the American Medical Association, by regularly organized State and local medical societies, and also by such general organizations relating to special departments and purposes as the American Academy of Medicine, the American Surgical Association, the American Gynæcological, Ophthalmological, Otological, Laryngological, Neurological, and Dermatological Societies, and the American Public Health Association; each of the foregoing Societies being entitled to appoint one delegate for every ten of their membership.

The members of all special and subordinate committees appointed by the General Committee shall also be entitled to membership in the Congress, together with such other persons as may be specially designated by the Executive Committee.

All Societies entitled to representation are requested to elect their delegates at their last regular meeting preceding the meeting of the Congress, and to furnish the Secretary-General with a certified list of the delegates so appointed.

2. The work of the Congress is divided into eighteen sections, viz.: 1. Medical Education, Legislation, and Registration, including methods of teaching, and buildings, apparatus, etc., connected therewith. 2. Anatomy. 3. Physiology. 4. Pathology. 5. Medicine. 6. Surgery. 7. Obstetrics. 8. Gynæcology. 9. Ophthalmology. 10. Otology. 11. Dermatology and Syphilis. 12. Nervous Diseases and Psychiatry. 13. Laryngology. 14. Public and International Hygiene. 15. Collective Investigation, Nomenclature, and Vital Statistics. 16. Military and Naval Surgery and Medicine. 17. Experimental Therapeutics and Pharmacology. 18. Diseases of Children.

3. The General Meetings will be reserved for the transaction of the general business of the Congress and for addresses or communications of scientific interest more general than those given in the Sections.

4. Questions which have been agreed upon for discussion in the Sections shall be introduced by members previously nominated by the officers of the Section. The members who open discussions shall present a statement of the conclusions which they have formed as a basis for debate.

5. Notices of papers to be read in any one of the Sections, together with abstracts of the same, must be sent to the Secretary of that Section before April 30, 1887. These abstracts will be regarded as strictly confidential communications, and will not be published until the meeting of the Congress. Papers relating to questions not included in the list of subjects suggested by the officers of the various Sections will be received. Any member, after April 30, wishing to bring forward a subject not upon the programme, must give notice of his intention to the Secretary-General at least twenty-one days before the opening of the Congress. The officers of each Section shall decide as to the acceptance of any communication offered to their Section, and shall fix the time of its presentation. No communication will be received which has been already published, or read before a Society.

6. All addresses and papers, read either at general meetings or in the Sections, are to be immediately handed to the Secretaries. The Executive Committee, after the conclusion of the Congress, shall proceed with the publication of the *Transactions*, and shall have full power to decide which papers shall be published, and whether in whole or in part.

7. The official languages are English, French, and German.

No speaker shall be allowed more than ten minutes, with the exception of readers of papers and those who introduce debates, who may occupy twenty minutes.

8. The rules, programmes, and abstracts of papers will be published in English, French, and German.

Each paper or address will appear in the *Transactions* in the language in which it was delivered by the author. The debates will be printed in English.

9. The officers of the General Committee on Organization are a president, three vice-presidents, a secretary-general, and a treasurer, and those elected to these positions will be nominated by the General Committee to hold the same offices in the Congress. All vacancies in these offices shall be filled by election.

10. There shall be an Executive Committee, to be composed of the President, Secretary-General, and Treasurer of the General Committee, and of four other members, to be elected by the General Committee. The duties of the Executive Committee shall be to carry out the directions of the General Committee, to authorize such expenditures as may be necessary, and to act for the General Committee during the intervals of its sessions, reporting such action at the next meeting of the General Committee.

11. There shall be a Standing Committee on Finance, composed of five members, to be appointed by the President, subject to the approval of the Executive Committee.

12. Those who are elected as chairmen of the several Sections shall be thereby constituted members of the General Committee.

The officers elected are as follows:

President.—Dr. Austin Flint, Sr., of New York.

Vice-Presidents.—Dr. Alfred Stillé, of Philadelphia; Dr. Henry I. Bowditch, of Boston; Dr. R. P. Howard, of Montreal, Canada.

Secretary-General.—Dr. J. S. Billings, U.S. Army.

Treasurer.—Dr. J. M. Browne, U.S. Navy.

The Executive Committee.—The President, the Secretary-General, and the Treasurer (*ex officiis*); Dr. I. Minis Hays, of Philadelphia; Dr. A. Jacobi, of New York; Dr. Christopher Johnston, of Baltimore; Dr. S. C. Busey, of Washington.

RECENT MEDICO-LEGAL NOTES.—A Massachusetts court not long since decided an interesting malpractice case, where the defendant, an irregular medical practitioner, treated a patient by applying, with her consent, flannels saturated with kerosene-oil. Under this treatment she died, and the physician was indicted for manslaughter and convicted. This verdict was appealed from on the ground mainly that, under the Massachusetts law, a person cannot be guilty of manslaughter unless he does some unlawful act, and that there was no law which prohibited any man

from prescribing for another with his consent, if he honestly intends to cure. The defendant also appealed from the judge's ruling that there need be no evil intent, but if, by gross and reckless negligence, the defendant caused the death, he was guilty of culpable homicide.

There seems to have been no question raised on the trial that the so-called doctor had little knowledge of medicine, and this lack of knowledge was asserted in his behalf as a reason for believing that there was no evil intent.

All of the objections raised were overruled by the Appellate Court and the conviction sustained.

A portion of the opinion is as follows: "In dealing with a man who has no special training, the question whether his act would be reckless in a man of ordinary prudence is equivalent with an inquiry into the degree of danger attaching to the act of common experience under the circumstances known to his action. It is here implied, and is undoubtedly true as a general proposition, that a man's liability for his acts is determined by their tendency under the circumstances known to him, and not by their tendency under all the circumstances actually affecting the result, whether known or unknown.

"Another cannot escape on the ground that he has had less than a common experience. Common experience is necessary to a man of ordinary prudence, and a man assuming to act as the defendant did must have it at his peril. Here the defendant knew he was using kerosene. More than that, he saw from day to day how it worked. The jury found that it was applied as a foolhardy presumption or gross negligence, and that is enough.

"When the defendant applied the kerosene to the person deceased in a way which the jury have found to be reckless, or, in other words, seriously and unreasonably endangering life according to common experience, he did an act which his patient could not justify by her consent, and which therefore was an assault, notwithstanding that consent."

In the recent case of Wm. C. Rhinelander in New York, who was charged with a murderous assault upon Mr. John Drake, the family lawyer, and who was alleged by his relatives to be insane, the unfortunate results of the present system of expert evidence were clearly shown. Mr. Rhinelander insisted with the greatest emphasis that he was perfectly sane, but, according to the New York Code of Criminal Procedure, when there is an allegation of insanity this point must be settled before the prisoner is called upon to plead to the indictment. A commission was appointed, which took many hundred pages of testimony, a large number of physicians being called by one side to sustain and by the other to overthrow the charge of insanity. A majority of the commission reported in favor of Rhinelander's insanity, but one of the commissioners said that he was perfectly sane, and this latter opinion was accepted by the court, which declared "that the expert evidence is of no value in this investigation. While the physicians called by the people to sustain the allegation of insanity say that the defendant is insane, they differ radically among themselves as to the classification of that alleged insanity. Two say he has general paresis, one says that he is an imbecile, and another that he suffers from melancholia. He cannot have all these conditions at one and the same time; insanity in its initial stages and in its progressed stages cannot coexist in the same person."

The English Court of Appeal has just decided as a question of law that the killing of the boy Parker by Captain Dudley, of the yacht "Mignonette," was not an act of necessity or self-defence, but murder.

It will be remembered that the yacht was lost in the South Pacific Ocean some months since, and the captain, two sailors, and the boy took to a boat. They were tossed about on the open sea for several weeks, and for nearly three weeks were without food, and for the last five days without water.

Under these circumstances, when the boy seemed to be fast sinking and there was every prospect that all would die, the captain killed the boy, and the survivors sustained life upon his flesh until they were rescued. The fact of the killing was not concealed, and did not appear to be considered criminal by Captain Dudley.

Upon arrival in England he was, however, arrested for murder, and the trial has just been concluded. The jury were charged by Baron Huddelestone, the judge, that the act was not self-defence or necessity, but the jury did not pass upon the criminality of the deed; they simply found the facts and recommended the mercy of the court. The question of law as to what the facts as proven constituted, whether murder or not, was reserved for the Court of Appeal, and this tribunal has just unanimously decided that the act is murder. Sentence of death has been pronounced upon the unfortunate captain, but it is probable that this sentence will be commuted. It hardly seems as if a person without food for nearly three weeks, and for nearly a week without water, is responsible for his acts. The strain under such circumstances upon the brain is awful to contemplate, and might well overpower all resistance of the will. There has never been a similar case in the courts, and the only one at all like it was tried some forty years ago. In that instance passengers were thrown overboard to lighten a boat, and the court decided that seamen not needed for the working of the boat should be sacrificed before the passengers, and that the doomed

men should be chosen by lot. As this was not done, the court held the case to be that of manslaughter.

IMPORTANT TO THOSE WHO USE MALT-EXTRACT.—W. W. Lamb, M.D., Chief Drug-Inspector of the Port of Philadelphia, writes that he has used Johann Hoff's Malt-Extract for the past five years in his private practice, and has found it a health-restoring beverage and tonic nutritive, being especially good for persons convalescing from fever, for cases of dyspepsia, for nursing mothers, and for weakly children, and also in lung-troubles. His attention had been drawn by the immense importation semi-monthly, and he states that about a million bottles imported by Eisner & Mendelson have passed his inspection in the Custom-House during the past five years.

A VALUABLE THERAPEUTIC SUGGESTION.—M. Dujardin-Beaumetz presented to the Société de Thérapeutique siphons of water, lemonade, and white wine, resembling seltzer water, excepting that oxygen replaced carbonic acid. They are recommended for gastric disorder, diabetes insipidus, and loss of appetite.

THE ANNUAL MEETING OF THE COLLEGE OF PHYSICIANS was held Wednesday, January 7, when the following officers were elected: President, J. M. Da Costa, M.D.; Vice-President, S. Weir Mitchell, M.D.; Secretary, Richard A. Cleemann, M.D.; Treasurer, Chas. Stewart Wurts, M.D.; Honorary Librarian, J. H. Hutchinson, M.D.; Recorder, J. Ewing Mears, M.D.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY held its annual meeting on the 7th instant. The following officers were elected: President, R. J. Levis, M.D.; Vice-Presidents, O. H. Allis, M.D., and De Forest Willard, M.D.; Secretary, H. Leffmann, M.D.; Corresponding Secretary, M. S. French, M.D.; Treasurer, L. K. Baldwin, M.D.; Librarian, C. M. Seltzer, M.D.

THE ACADEMY OF SURGERY held a stated meeting on the 7th instant, at the College of Physicians, when Dr. John H. Packard delivered the annual address.

GOLD MEDAL AWARDS TO UNITED STATES PRODUCTS.—Among the food-products exhibited at the International Health Exhibition, London, 1884, from the United States, were beef-peptonoids and maltine. Both of these preparations carried off the only gold medal and highest award against numerous competitors in their respective classes. All food-preparations were critically analyzed at this exhibition by a jury composed of the best chemists in the country.—*London Lancet.*

LONDON LECTURES.—Dr. Osler, of Philadelphia, will deliver the Gulstonian Lectures for 1885 at the College of Physicians; Dr. Herman Weber will deliver the Croonian, and Sir Andrew Clark the Lumleian Lectures.

NOTES AND QUERIES.

MEDICATED TAMPONS IN DISEASES OF WOMEN.

1504 WALNUT STREET, PHILA.

MR. HARRIS, of H. C. Blair's Sons, cor. Eighteenth and Chestnut Streets, has made for me, with great care and skill, some valuable cotton tampons, which I have used in conveying various substances to the vaginal walls and uterus, and also in a measure giving support to the congested and inflamed tissues until they became more tolerant to a pessary. These tampons are made of masses of absorbent cotton, salicylated, borated, carbolized, and thymolated, folded into conical shape, and coated with a preparation which keeps them in form so as to be easily introduced until they come in contact with the heat and moisture of the tissues. To each a string is attached firmly, by which it can be removed. They can be introduced preferably with a speculum if it is necessary to place them in a special position, and I usually dip them for an instant in hot water if the vagina is very dry and inflamed. Otherwise I coat the truncated end of the cone with a small quantity of vaseline, or with the glycerole of tannin or of sanguinaria if these substances are required.

These tampons are also used to convey iodoform to the tissues. Twenty or thirty grains of iodoform are placed in the centre, and after the shape is given to the mass very little odor is perceptible; but the heat of the body at once volatilizes the iodoform and brings it in direct contact with the mucous membrane. These tampons will not become offensive, and can be allowed to remain *in situ* a week or more. This is especially valuable when a number of them are used to correct displacement.

To those who have read Professor Parvin's excellent paper before the Lehigh Valley Society (*Phila. Med. Times*, vol. xv., page 8) the uses of pledgets of soft antiseptic materials in the vagina are well known. They absorb secretions, convey antiseptic and other substances directly to the mucous membranes; they deplete inflamed tissues, separate surfaces which mutual contact irritates, and in certain cases relieve the tension on the uterine ligaments which may themselves be congested or inflamed by supporting the heavy uterus, and thereby allowing medication, both internal and local, to relieve the engorgement and restore tonicity to those tissues and the vagina. Also in old displacements where adhesions have taken place careful packing and gradual restoratives will be required before a hard support can be worn. For this purpose Mr. Harris has made some tampons of fine-carded wool, borated, which, being impervious to water and antiseptic, can be placed *in situ* and act mechanically.

With considerable experience, I am satisfied that much can be done by the proper use of these measures.

J. M. KEATING, M.D.,
Visiting Obstetrician to the Philadelphia Hospital;
Surgeon to Maternity Hospital.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM DECEMBER 21, 1884, TO JANUARY 3, 1885.

MCPARLIN, THOS. A., LIEUTENANT-COLONEL AND ASSISTANT MEDICAL PURVEYOR.—Granted leave of absence for three months, on surgeon's certificate of disability. S. O. 301, A. G. O., December 24, 1884.

GIRARD, A. C., CAPTAIN AND ASSISTANT-SURGEON.—Ordered from Department of the Missouri to Department of the East. S. O. 304, A. G. O., December 29, 1884.

JOHNSON, HENRY, CAPTAIN AND MEDICAL STOREKEEPER.—Directed, in addition to his present duties, to perform the duties of Assistant Medical Purveyor in New York City. S. O. 301, A. G. O., December 24, 1884.

WALES, PHILIP G., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty in Department of the Columbia, and ordered to Department of Arizona. S. O. 128, Division of the Pacific, December 17, 1884.

EWING, CHAS. B., FIRST-LIEUTENANT AND ASSISTANT-SURGEON (Fort Stanton, New Mexico).—Granted leave of absence for two months. S. O. 304, A. G. O., December 29, 1884.

NAVAL MEDICAL OFFICERS.

There were no changes in the Medical Corps of the U.S. Navy from December 21, 1884, to January 3, 1885.

PHILADELPHIA, JANUARY 24, 1885.

ORIGINAL ADDRESS.

THE GREAT ADVANCES IN SURGERY, AND HOW THEY HAVE BEEN MADE.

Being the Annual Address before the Academy of Surgery of Philadelphia, delivered January 5, 1885,

BY JOHN H. PACKARD, M.D.

MR. PRESIDENT AND GENTLEMEN,—Among the paintings in the rotunda of the Capitol at Washington, there is one which purports to represent the discovery of the Mississippi River by De Soto. Mounted upon a splendid prancing steed, the commander is advancing into a cleared space upon the bank; around him, in glittering armor, are soldiers, some of whom are dragging forward a brightly-burnished brass field-piece; beautiful Indian girls are presenting offerings of flowers and fruit; while chiefs and braves, in all the glory of feathers and paint, are looking on in stolid wonder at the scene.

It seems to me, however, that the artist has totally failed to apprehend or to set forth the true character and grandeur of the event. De Soto and his men, according to the most authentic accounts, had heard rumors of the great river, and had been for weeks struggling through the swamps and forests on their toilsome way in search of it. Weary and worn out, almost ready to give up in despair, they at length found themselves upon its banks, the object of all their labors and hardships attained. We can imagine the forlorn little band of adventurers, hungry and exhausted, with ragged clothing and rusty arms, but every gaunt face lighted up with the joy and exultation of success, as they gazed on the mighty current rolling towards the sea. Mighty as that stream was, it was less sublime than the human energy which had overcome every obstacle to find it, and whose servant it was thenceforth to be.

Other examples of like misconception of historical events might easily be adduced, and it may be that there are very many of them. Actions, perhaps in themselves trivial, which lead to momentous consequences, are apt to be magnified by the medium through which they are afterwards viewed. When the Yankee farmer, crouching behind a fence, fired his old fowling-piece at the officer commanding a squad of British soldiers, he little imagined that the echoes of his shot would be heard all over the world. We see now that he began a contest which was to give freedom to unborn millions and to establish a vast nation, and we are inclined to rank him as a hero. Of all this he knew nothing. It is very possible that he heartily regretted his rash action; he may have even denied it, at times when the Continental cause seemed threatened with ignominious failure.

Much the same sort of illusion is apt, as it seems to me, to invest the prominent events in the onward progress of the science and art of surgery; and my purpose this evening is to consider these great advances, with the actual circumstances attending them. I have found it somewhat difficult to select a title which should define my subject without seeming to promise more than I could hope to perform. But indeed the actual number of such marked strides is curiously small,—smaller, I think, than is generally realized.

Another striking instance of the glamour with which past events are wont to be surrounded is to be found in the well-known picture in the École de Médecine in Paris, representing Ambrose Paré applying the ligature for the first time to check bleeding after amputation. The great surgeon stands in front of a patient whose leg has just been removed. Among the by-standers are several high dignitaries, one of whom offers Paré a heated iron, which he declines, holding aloft in his right hand a bundle of ligatures, which he is about to use.

No such scene, however, can be found described by the chief actor, who, we may be sure, would have put it upon record had it taken place. The honest old man was not averse to chronicling his triumphs, as well as the impression they made upon the spectators. As to his introduction and advocacy of the ligature he speaks at much length, but with as much modesty as conviction. The twenty-fourth chapter of his twelfth book is devoted to this subject. "Verily, I confess," says he, "I formerly have used to stanch the bleeding of members, after amputation, after another manner than that I have a little be-

fore mentioned: Whereof I am ashamed and aggrieved. But what should I do? I had observed my Masters, whose method I intended to follow, always to do the like." He then describes the suffering and the bad results which attended the use of the actual cautery, and concludes: "Wherefore I must earnestly entreat all Chirurgeons, that leaving this old and too too cruel way of healing, they would embrace this new, which I think was taught me by the special favour of the Sacred Deity; for I learnt it not of my Masters, nor of any other; neither have I at any time found it used by any: Only I have read in *Galen* that there was no speedier remedy for stanching of blood than to bind the Vessels (through which it flowed) toward their roots, to wit, the Liver and Heart. This precept of *Galen*, of binding and sewing the Veins and Arteries in the new wounds, when as I thought it might be drawn to these which are made by the amputation of members, I attempted it in many; yet so, that at first in my budding practice thereof, I always had my cauteries and hot Irons in a readiness, that if anything happened otherwise than I expected in this my new work, I might fetch succour from the ancient practice; until at length confirmed by the happy experience of an almost infinite number of particulars, I bid eternally adieu to all hot Irons and Cauteries which were commonly used in this work."

Against the new method of hæmostasis there was a particularly virulent objector, one Gourmelen, whose name is otherwise unknown. This man's words Paré quotes in his twenty-ninth book, and then, after some argument, relates several instances in which the ligature was used by his direction, in each case mentioning the operator by name. Unquestionably, had there been any such brilliant exhibition of the novel practice as the painter has undertaken to represent, it would have found a place among these; and the conclusion is unavoidable that it was imaginary.

Paré's official standing was so high, and his influence so great, that one might suppose a change of practice which had his sanction would have been at once effected wherever it became known. Moreover, the method was not really a new one. There are not wanting those who believe that Celsus, who mentions the ligature as a means of checking hemorrhage in accidental wounds, had employed it also after amputation; and that he omitted distinct mention of it in the thirty-third chapter of his seventh book, in describing the removal of gangrenous parts, simply for the sake of conciseness. But Celsus was not only concise; he was also thorough, and would scarcely have left so important a matter to be inferred from other passages in his writings. And the plain meaning of the concluding sentence in the place above referred to is, that after the first dressing, amputation-wounds should be treated like others in which suppuration is to be expected.

So far was the great and practical step advocated by Paré from being generally or immediately appreciated, that nearly two hundred years after the operations recorded by him, we find Samuel Sharp, Assistant-Surgeon to Guy's Hospital, speaking of the actual cautery as follows: "Within these last fifty years this barbarous Practice has by degrees fallen into Disuse, both in France and England; but it is not absolutely discarded in every part of Europe." Hence it was at least one hundred years after a man, so eminent as Paré was recognized to be even in his own day, had made an urgent and really eloquent appeal on behalf of the ligature, before any general abolition of the cautery could be effected. Mr. Sharp, after presenting various arguments and combating various objections to the tying of arteries, thus concludes: "I hope I shall not be censured for labouring to establish a Point which no Man of Eminence in London contradicts. It is a sufficient Apology for me, that the Writings of the ingenious Surgeons I allude to, being in the Hands of our English Students, may possibly mislead them, if not warned against the Danger. Besides, Improvements of all kinds are so slowly propagated, that this, amongst others, is not Universally practised in the distant Counties of our own Kingdom; and therefore a further Enforcement of its Advantages will not, I believe, appear to be a useless Undertaking."

One would suppose from the words just quoted — the concluding ones of Mr. Sharp's original work — that he was a man thoroughly persuaded in his own mind as to the value and reliability of the ligature. Yet in his fourth edition there immediately follows a postscript, added for the purpose of noticing a new remedy,

—agaric,—with the declaration of opinion upon it by the French Royal Academy of Surgery, on the strength of which the inventor, M. Brossard, received from the king a gratuity and a pension. Mr. Sharp says, "As it hath not yet been sufficiently practised on the Femoral Artery, to warrant the Recommendation of it on large Vessels, in preference to the Ligature, I have forborne to speak of it in the Body of the Book. Should it hereafter be found equally secure with the Ligature, it would certainly be a most useful Discovery," etc.

This last passage seems to me to be singularly illustrative of a sort of almost superstitious credulity as to the special powers of medicinal agents, which stamped strongly the views of the older writers, growing, however, gradually less and less marked, until in our day it has given place to a scepticism which may indeed be far more philosophical, but which is certainly far less comfortable as a basis for therapeutics.

But I will ask you to let me recur again to the strange history of the matter we have had under discussion, which it is difficult for the modern mind—might I say for the American mind?—to comprehend.

Celsus, in the first century of our era, spoke of the ligation of arteries, in accidental wounds at least, not as being a new thing, but as a recognized procedure. How long it had been known before his time does not appear. It is mentioned again by Galen, and in the seventh century by Paul of Ægina. Yet not only these great men, but all their contemporaries, and those who followed them, continued to use vitriol buttons, cauteries, and like means for checking the flow of blood after amputations; it was reserved for Paré, in the sixteenth century, to extend the simple and familiar idea of the ligature to cases of the latter class. It would seem, indeed, as if this were but a small step to take, and one easy to follow. That it was not lost sight of, we learn from the writings of Le Clerc, Daniel Turner, and Gooch, in the eighteenth century. It must have been taught in the London schools; and yet scarcely a hundred years ago one of the surgeons of Guy's Hospital thought himself called upon to argue in its behalf, saying that there were in England many who had not yet abandoned the old and cruel practice.

It may be even more impressively stated in another way. The ligation of arteries in accidental wounds was known in the time of Christ, but the idea was not applied to amputations until after the founding of the Royal College of Physicians in London, nor did this use of the ligature become universal until almost within the time of persons now living.

We are fain to think that such blindness at this day would have been out of the question; and, indeed, it seems inconceivable to the inquisitive, progressive, and practical spirit of our age,—impossible with the glare of light which modern customs and appliances have brought to bear upon all subjects of study, and with the existing facility of interchange of ideas. We flatter ourselves that had Paré lived in our time, and introduced such an improvement in surgical practice, the idea of the painter would not have been so very far out of the way, and the great step would at once have been taken with all the *éclat* with which he imagined it to have been surrounded. But we must not forget that our standpoint is very different from that of his contemporaries, and should have charity for their conservatism.

The science and art of surgery have been built up, as we now have them, by observation and invention. Yet this expression is hardly correct. In the construction of a building the workmen are guided by a plan. The architect has a definite idea in his mind of what the result is to be, and to the carrying out of this every man's task is subordinated. No such plan can exist in a science which has to deal with constantly varying conditions, with an incalculable number of combinations; or in the art associated with that science.

We have, however, a vast mass of experience, accumulated and recorded by hosts of workers, past and present, and marshalled into a sort of order by those whose abilities and position have qualified them for the task. Certain general principles have thus been evolved, which constitute the body of surgical science. Yet if one were to undertake to set down absolutely unquestionable doctrines or principles only,—fixed facts, which it is certain cannot by any further degree of research be changed or set aside,—he would find that the resulting material would be of very small bulk indeed. What had seemed to be a stately building would turn out to consist of a very few stones, with a shapeless and

irregular, because temporary and mutable, scaffolding over them.

This statement may appear to be very disparaging to the immense amount of surgical literature; but in fact this is made up largely of history, and of quotation of the recorded experiences and opinions of others. Especially is such the case in this age of bookmaking; and the difficulty is not that there is so much that is new to be read, as that it can scarcely be separated from the old with which it is mixed. The books which have really been great additions to the world's stock of knowledge have been but few, almost as few as the great advances in surgery, which we are now engaged in considering.

A great step in surgery is taken when a new procedure, adapted to various morbid conditions, is devised, or when a procedure already known is extended in its application to one or more classes of cases which are of frequent occurrence, and which have previously been looked upon as intractable.

Such a step was taken by the surgeon, whoever he may have been, who first amputated a limb for other cause than gangrene. Among the ancient surgical writers we find no mention of any such operation. Their idea was simply to separate dead parts, incising through them only, and trusting to the cautery to destroy what was left up to the still living tissues. In the Book of Deuteronomy, however, it is commanded that as a punishment for a certain immodest act, the hand of a woman should be cut off; and in the Book of Judges the maiming of captives by cutting off their thumbs and great toes is spoken of as having been done in seventy-one cases. In neither instance is there any explanation given or comment made, and we are left to infer that operations of this kind were not unfamiliar to those who received and preserved these writings. One can scarcely help speculating whether the civilization of the ancient Egyptians, Persians, or Hindoos may not have included surgical skill in the treatment of the accidents met with by those engaged on their vast architectural works. That they had mechanical knowledge which perished with them cannot be doubted, yet this must have been familiar to great numbers of workmen, and continually seen by the people, whereas medicine and surgery, being in the exclusive possession of the priestly or other privileged classes, and being of necessity private in their exercise, would have been far more likely to be lost with the decadence of the nations. Perhaps we are too ready to assume that a basis of anatomy and physiology must have been wanting to any such ancient system of surgery, although the tendency of the religious beliefs of that day, so far as we know them, was strongly opposed to the desecration of the human body involved in its dissection. Possibly there were burnt in the Alexandrian Library records which would show that our most recent improvements are really only revivals of things familiar to the physicians of the Pharaonic times. All this, however, is of course mere conjecture.

With the loss of simplicity in habits of life, with the introduction of fire-arms, and in the present century with the invention of steam machinery, the occasions of amputation have very largely increased, and improvements in its mode of performance were inevitable. But not one of these changes has equalled in magnitude the first step,—the demonstration that a diseased or injured limb might be removed without waiting for its death, and that by this removal the life of the whole organism as such might be preserved.

In connection with the subject of amputation, and recurring for a few moments to the checking of hemorrhage after it, let me remind you that both Galen and Paul of Ægina advise that if a wounded vessel be large it should be seized with a hook, stretched, and twisted moderately. It seems to me that this expression could hardly refer more distinctly to the tenaculum as we now have it; yet by some modern writers the invention of this instrument is credited to Bromfield, in the last century.

And let me digress for a few moments to refer to certain improvements which, while valuable, cannot be regarded as great steps in the true sense of the term. One instance only will suffice.

Paré figures what he calls "the crow's beak, fit to draw the vessels forth of the flesh, so that they may be tied." This instrument was merely a pair of nippers with flat blades, ridged or roughened at their inner sides near the ends, so as to give

them a secure hold. The opening and closing of the blades required a separate movement of the hand. Le Clerc speaks of forceps having a spring, or the *valet à patin*, this latter being a ring slipped down over the blades, so as to keep them closed. The spring was perhaps the invention of Assalini. Then it occurred to some one to make the two branches spring outward, so that the instrument was open unless pressed together. A further advantage was gained by adding a slide, so that the blades, brought together by pressure between the thumb and finger, could be fastened thus, the whole process being effected with one hand. And by making the ends bulbous, the risk of including the instrument in the ligature was done away with. For special purposes, the ends were very early made toothed.

Now, here was a succession of improvements, resulting in a very perfect instrument, having a very wide range of application; and yet neither the whole process nor any one of its successive steps could be at all regarded as a great advance in surgery. There was no great principle involved in either the construction or the use of the instrument; it was a mere device for subordinate purposes.

To return for a moment to the subject of amputation. When the idea was conceived that the soft parts might be so divided as to insure an ample covering for the bones, it was so much of an improvement as almost to come within the range of our great advances in surgery. But it was not new; it was only a suggestion for the carrying out of a principle which was abundantly recognized already. And the same may be said of the flap method, with all its subsequent modifications; the admirable stumps so often obtained by the circular incision, when properly carried out, have not been surpassed by the results of operations done with the flap, which in fact has only the advantages of greater convenience, of more rapid execution, and sometimes of adaptability.

The introduction of excision of bones and joints was properly a great step in surgery. Its history is curiously like that of some other operations of high value. Filkin, who in 1762 excised the knee-joint, was without followers for nearly twenty years, when his procedure was imitated by Park, with a success which made him an enthusiastic advocate of the measure, and led him to extend its use to the other articulations. The Moreaus, father and son, in France, practised it largely, and, I believe, with gratifying results. Other French surgeons imitated them, and later the operation found promoters in Liston, Syme, and other British operators. In this country, although many joints have been excised to the saving of useful limbs, we may claim more in the way of successful excisions of bones, beginning with the brilliant achievement of Dr. John Rhea Barton, of this city, in 1826, on the anchylosed hip of a sailor. For many of the deformities due to anchylosis, as well as to distortions of the bones, the more modern operation of subcutaneous osteotomy answers better; but I shall have occasion to mention this again.

I am aware that there are not a few surgeons who are inclined to regard the excision of joints with disfavor, on account of the trouble and risk involved in them, and the uncertainty of the ultimate result in any given case. Yet the many instances of perfect recovery with useful limbs,—far more useful than any artificial substitutes could ever be,—and hence the inference that due care only is needed in the selection of the patients to be submitted to such operations, warrant us in assigning to the introduction of these procedures a place among the great advances in surgery.

I shall next refer very briefly to a great step in advance, made by one of the ablest men who has ever adorned the profession of medicine. When John Hunter, in 1785, tied the femoral artery for a popliteal aneurism, he initiated a practice destined, in various forms, to be of vast service in the treatment of a disease for which there had previously been no known remedy. He based the procedure upon a thorough knowledge of anatomy, and upon the most philosophical reasoning; and since his first attempt, which was crowned with brilliant success, the labors of subsequent surgeons in this field have been almost altogether in the direction which he indicated. Instrumental compression, digital compression, and other modifications of means for carrying out the great principle which he laid down, have as yet yielded the best fruits. It would be foreign to my present purpose to speak of the experiments which have been made in other lines, even

if they had been more extensive or more satisfactory than they have yet proved.

I will barely mention subcutaneous surgery, which in the period of a little over fifty years since its introduction by Stromeyer has been so greatly extended in its uses, especially within the last two decades. It was certainly an advance of great importance.

Plastic surgery has made such advances in special directions, within the last half-century, as can scarcely be overlooked. I refer particularly to the operations devised, and successfully carried out, for the relief of vesico-vaginal fistula and of ruptured perineum. The limits of this field have not yet been reached. It is claimed that much good may be effected by suture of the lacerated cervix of the womb, and the already large number of cases in which it has been done with apparent benefit seems to warrant the belief that the claim may be substantiated. I presume there is hardly a surgeon who hears me to-night but has repeatedly been called upon to perform this operation, one of the newest on the list.

No enumeration of the great steps in our art would be complete without reference to abdominal surgery, and especially to its most important feature,—ovariotomy. I know of no more instructive portion of the history of medicine than that relative to the rise and progress of this procedure. Spoken of for two hundred years as a thing that might be done—perhaps, it was first carried into effect by a man whose merit was far greater than his fame. His teacher, the great Hunter, had suggested it in his hearing; and after his return to Kentucky, McDowell had the courage to attempt what others had only thought of. Three out of four lives did he save before he wrote an account of what he had done; and his modest statement was received with the utmost scorn and contempt by the then leading journal of the world.

Without knowing of Dr. McDowell's case, Dr. Nathan Smith, in 1821, performed an ovariotomy, and thus, although anticipated, may claim an equal originality.

I shall not detain you over the history of this operation during the next thirty-five years, but will merely say that the admirable account of it given by the late Dr. Peaslee will well repay careful perusal. At about the end of this period, in 1857, the subject was brought up for discussion in the French Academy, and the following eminent names may be found among those of the most determined opponents of the practice: Boyer, Velpeau, Huguier, Moreau, Jobert, Malgaigne, and Cruveilhier. One only, Cazeaux, spoke of it as perhaps sometimes justifiable. The statistics at this time stood: in America, 97 operations, 54 successes; England, 123 operations, 71 successes; Germany, 47 operations, 13 successes.

One more statement: When one of the leading British ovariotomists, Mr. Spencer Wells, was knighted, a year or two since, he was complimented upon having added an aggregate of twenty thousand years to the lives of British women. I need hardly comment upon the facts now mentioned; but it seems to me that Ephraim McDowell, in the little town of Danville, in Kentucky, took a step in 1809 which entitled him for all time to rank among leaders in surgery; and if "Peace hath her victories, no less renowned than War," I think he may be assigned a place above many of those who have gained their laurels on the battle-field.

Of some other matters in abdominal surgery, — gastrostomy, cholecystotomy, nephrectomy,—it is as yet too early to judge. They promise, but they have not yet performed.

One great step will probably be taken at some future day in this direction, in the surgical treatment of intestinal obstructions. According to the *British Medical Journal*, July 19, 1884, the first definite and deliberate proposal to open the abdomen in search of an obstruction in the intestine was made by Barbette, in 1672. The first operation of the kind is recorded by Bonetus, in his "Sepulchretum," published in 1677. The first operation performed in England was by Sir B. Brodie, the abdominal cavity being opened in the middle line, for the relief of a hernia of the bowel through a rent in the rectum: it was unsuccessful.

Perhaps the greatest advance ever made in surgery was in the introduction of anæsthesia. The history of this wonderful event has been so often written upon, and so largely discussed, in view of the conflicting claims to its inception, that the mere mention of it is sufficient. It has been said that printing is "the art preser-

vative of all arts," and anæsthesia seems to hold a somewhat analogous position towards the rest of surgery.

Let me mention, as a curious fact, that rectal anæsthesia, generally considered one of the most recent of surgical expedients, was really proposed about forty years ago, and by no less an authority than Pirogoff. Although known to Roux in Paris, and experimented upon by other surgeons, the method was not long employed even by its inventor, although he occasionally continued to use it in allaying nephritic colic.

I would refer to what seems to be a great advance now in progress in the surgery of the chest, in the treatment of various affections of the lungs and pleura by surgical operation. This has the usual history. Krönlein states that in 1812 Richter asked, "Why should not lung-abscesses be opened externally?" and said that it had been done successfully by Benjamin Bell. Such was indeed the fact, and again an American was well up towards the front, for in 1823 Milton Antony published, in the *Philadelphia Journal of the Medical and Physical Sciences*, a case in which he removed, along with a diseased rib, a large portion of lung-tissue which was involved. Krönlein's case was that of a girl with a recurrent sarcoma, in which a zone of healthy lung-tissue was removed along with the growth, by means of scissors. The wound in the lung was united with catgut sutures, and in one month the patient was dismissed cured.

I must not omit to mention the great advance in the surgery of the genito-urinary organs in the development of lithotrity, the merit of which was practically due to Civiale, or the almost equally great step made by our countryman, Dr. Bigelow, in showing the tolerance of the bladder, and experimentally proving that a stone may be crushed and removed at one sitting.

In special departments of surgery there have been some great advances made to which I can but allude, such as iridectomy, the use of the ophthalmoscope, and the correction of disorders of accommodation in the eye. The laryngoscope, and the means of removal of tumors in the air-passages, are instances of such improvements. But, valuable and important as they are, they belong so entirely to special departments that I cannot dwell upon them.

Perhaps some of you, gentlemen, will wonder why I have not spoken of antiseptic surgery, so called, as a vast advance upon all that preceded it. Others possibly will think that it need not have been mentioned at all. And it is precisely for this reason that I have left it to the last. It is still *sub judice*. Its able author and advocate has certainly shown the value of cleanliness, absolute as well as apparent. He has won over a very large and enthusiastic following to his peculiar views. Yet it remains to be seen whether the objects to be sought for, and claimed to be thus secured, may not be more effectually attained in other ways. The doubt thus expressed involves not only the method, but also the principle upon which it is based; and the time has not yet arrived for deciding the question.

I had intended, but time fails me, to speak not only of the great advances actually made in surgery, but of those also which have seemed to be such, but which have failed to stand the test of experience. Among these the most notable instances are acupressure, torsion of arteries (really of ancient date), syphilization, and *écrasement linéaire*. We are prone to judge hastily, to think we have found gold-bearing ore when the supposed prize turns out to be but spurious and fit only to be thrown away. Only very rarely is the precious metal found in ingots on the surface; generally it must be acquired by hard labor, and sometimes it is passed over unrecognized even by earnest seekers.

To one entering upon the study of medicine, the vast field which opens before him is apt to be bewildering. Yet as he becomes more familiar with it he grows more confident, until it seems to him that he has only to march in and occupy the land. To his ardent gaze, the problems which have puzzled the wisest heads and baffled the deepest research seem but to await solution. The untried energy burns to scale the heights, to triumph over the obstacles, to make the crooked straight, and the rough places plain. How different the scene as it is closely approached! and when, as this evening, we look back and see how few have been those triumphant advances, how slowly and with what difficulty they were effected,—difficulty not always inherent in the task, but born of envy or ignorance,—we cannot but wonder that there still exists such enthusiasm.

Yet enthusiasm is not the best of the forces for maintaining our onward struggle; and there takes its place, as one moves on, the sober conviction of the genuineness of certain principles, the love of science which is engendered by faithful work for it, and verily we may say that the last state of that man is better than the first. We "learn to labor and to wait,"—to do our duty as best we may, trusting to the future for our reward.

Mr. President, I cannot conclude without some reference to the memory of one who has gone from among us, whose noble presence and genial influence have often graced our meetings. With untiring energy his comprehensive mind was always gathering up whatever of new truth might be added to the common stock. He preserved in a most unusual degree the receptive spirit which is in accord with all progressive movement, and closed his long and useful career almost in the very act of presenting to the American Surgical Association a communication on an important subject.

I am sure that the recollection of our founder's influence, of his venerable face and form, will be ever cherished by those of us who have had the privilege of intimate contact with him, as incentives to earnest labor in the cause of surgical science, which was so dear to his heart.

ORIGINAL COMMUNICATIONS.

INVERSE TYPE OF TEMPERATURE IN TYPHOID FEVER, WITH A REPORT OF TWO CASES; TEMPERATURE-PECULIARITIES IN EPIDEMICS, WITH A REPORT OF SEVEN CASES IN ONE FAMILY.

Read before the Philadelphia County Medical Society, November 26, 1884,

BY W. C. HOLLOPETER, M.D.

THE classical investigations of Wunderlich, Thierfelder, and Traube have done much to simplify the study of fever, and by their deductions they have rendered it possible for us to differentiate typhoid from all the other continued fevers by its temperature alone. This universal tendency to refer a given symptom to an established, or partially-established, law has done much to lessen the interest of individual work; for those cases marking the exception are, as a rule, looked upon as complications, and slight causes are frequently brought forward to explain the apparent departure from the established rule. Dr. J. C. Wilson, in his admirably-written work on "The Continued Fevers," tells us that "marked deviations from the typical course of the temperature are always due to special causes. These causes, in many cases, cannot be discovered by the most searching investigation. On the other hand, upon inquiry, clinical facts of importance are often discovered, and it is therefore the duty of the physician, in every case when marked deviations occur, to make diligent search for their cause."

I enunciate a well-recognized fact when I state that every physician in general practice has had cases of typhoid fever where the temperature-record has been irregular, when, at the morning or the evening visits, the thermometer has registered the same, or has shown some unusual features in the evening exacerbation or morning remission, departing in some unsatisfactory manner from the gracefully-arched curve of Wunderlich.

It has frequently been my lot to treat cases of fever having every symptom of typhoid, yet not responding to the well-marked type of temperature as described by Wunderlich. For a long time it was very difficult to assign any cause for the variation, although it is natural for complications to disturb the rule, especially when we anticipate a typical curve in the temperature-chart.

Dr. Wm. Pepper has stated, in a recent clinical lecture, that "it was the exception, and not the rule, to find a typical case of typhoid fever." Although every symptom may be uncertain, or even frequently wanting, in some cases of typhoid fever, yet I believe the temperature, the peculiar form especially, remains the most constant factor, and, as Griesinger states it, "generally controls the situation."

During the last seven months I have had under my care a case of typhoid fever in which the temperature-record corresponded to the "inverse type," as described by Traube.

Bäumler, in drawing attention to this unusual character of the temperature, states that, in the great majority of cases, the daily fluctuations follow the rule of health, the exacerbation taking place in

the evening. We sometimes meet with cases where this order is reversed, the rise taking place in the morning and the remission occurring in the evening.

This "inverse type"—so named by Traube—of the daily fluctuations of a febrile temperature has been observed in some rare instances in typhoid fever.

I have been unable to find any additional reference to this unusual type of temperature in the systematic treatises on fever. Liebermeister and Murchison do not mention it in their works, nor have I been able to find any clinical reports bearing on the subject in any of the medical journals.

The clinical notes of my case are as follows:

Frank M., aged 14, of thoroughly healthy parents, was taken ill May 15, 1884. My friend Dr. Schoales, being the family physician, was sent for. The doctor was indisposed at the time, and I was requested to take charge of the patient. I found that the boy had been sick for two days, a slight chill occurring three days previous, and ever since he had been feverish, restless, and stupid; he had refused food and complained of headache; he had also slight nose-bleed and loose bowels. The history of the case was not unusual, having every well-marked typhoid symptom, and was of interest in the character of the temperature alone, which was as follows:

	A.M.	P.M.	Pulse.
May 15 . .	102⅘°	102°	100
" 16 . .	104	103⅖	108
" 17 . .	103½	103	108
" 18 . .	103⅘	102⅖	112
" 19 . .	105⅖	104	116
" 20 . .	104⅗	101⅖	96
" 21 . .	103⅗	102⅘	108
" 22 . .	100	102⅕	96
" 23 . .	99⅘	99	96
" 24 . .	100⅘	100	96
" 25 . .	101⅗	101	96
" 26 . .	101⅘	101	100
" 27 . .	98⅘	99⅕	100
" 28 . .	100	99⅖	100
" 29 . .	100⅕	99	100
" 30 . .	101⅗	99	98
" 31 . .	101	97⅖	98
June 1 . .	100⅘	99	100
" 2 . .	98	98⅖	98
" 3 . .	98⅖	97⅖	98

In this case the boy had been complaining for a few days, according to the statement of the parents, before advice was called in. How much longer he had been ill we are unable to state, but, judging from the elevation of the first temperature (102⅘°), the case was evidently well on in the first week.

The exacerbation recurring so regularly in the morning, and the remission taking place as faithfully in the evening, caused me to watch the case with unusual vigilance. We could hardly be mistaken in the character of the fever,—Dr. Schoales subsequently visiting the case with me frequently and corroborating the diagnosis. The stupid and listless countenance; the distended and tympanitic abdomen; the rose-colored spots, few, but constant throughout the illness; the gurgling in the lower portion of the abdomen; the loose bowels; the nose-bleed; the deafness,—all conjoined to render the diagnosis certain. Then the duration of the illness, while not very severe, extended over four weeks, which corresponds to the average duration of uncomplicated typhoid fever.

The treatment of the case was such as to have but little effect on the temperature, except to lower it: diet exclusively of milk and milk food; the recumbent position faithfully maintained; large and well-ventilated room, thoroughly disinfected. No drug was used likely to influence the fever, with the exception that, during the prevalence of the highest records, thirty grains of quiniæ sulphatis were exhibited in ten-grain doses, two hours apart, during the night. This was ordered on three successive evening visits. Cold-water sponging of the body was continued frequently as long as the temperature remained above 102°. We were unable to discover any complications whatever; in fact, there were none,—no bronchial irritation, no disturbance of the alimentary tract. The course of the fever was so uniformly regular, the various symptoms occurring in their usual order, and the whole phenomena of the fever convincing as to its character, except the very important factor noticed in the *inverse type* of temperature.

The want of uniformity in the temperature-record of the case just noticed recalls the facts in a patient I had under my care nearly three years ago. The clinical notes recorded on the back of my temperature-sheet at the time are briefly as follows:

Walter, æt. 7, was a well-developed boy, and the youngest in an exceedingly healthy family. The mother informed me that the boy had commenced to manifest a disinclination for food and play five days before any trouble was suspected. I was therefore called in on the evening of the fifth day. I found the little fellow quite delirious, with a temperature of 103⅖°, a full pulse of 130, respirations 26, face flushed and apparently swollen, eyes congested, skin dry and hot, bowels confined. Ordered a fever-mixture.

In the morning temperature had fallen to 100⅕°, pulse 100. The patient had relapsed into a quiet sleep during the early morning hours. The skin had become moist. On a more careful examination I found the abdo-

men tender, somewhat tympanitic, and distended. The mother stated that there had been during the past ten days occasionally slight nose-bleed. The bowels showed a disposition to be free, yet, while not constipated, they had not been open regularly every day; now one or more free movements occurred daily. The third day, end probably of first week, if not more, the temperature, with a single exception, did not go above 102°, but had a gradual decline. The interesting feature was the morning record, which was higher than the evening. This unusual feature continued for twelve days. The amount of variation was from one to one and a half degrees.

On the twelfth day, about the twentieth of the attack, the morning temperature reached 103° without any other unusual symptom, after which it changed and ran as a typical case of typhoid fever in convalescence: morning 100°, evening 102°; morning 98⅘°, evening 101⅖°, etc.

The downward curve was thus continuing uninterruptedly until the seventeenth day, when the temperature ran up to 102° again; following this rise the morning record marked 98°, and an intestinal hemorrhage of over four ounces of dark blood following an unusually large fæcal movement.

The thermometer never registered a temperature after this above 100°. The case made a good recovery, convalescence slow. In this case we had a temperature-curve closely following an ordinary typhoid-fever chart, with the unusual exception of the twelve days of *inverse type*, with no discoverable complications to explain the cause.

I have not deemed it expedient to enter into an accurate analysis of each and every symptom of the foregoing irregular cases, knowing it to be exceedingly burdensome, yet I hope that I have sufficiently outlined the general features of typhoid, the phenomena of which are so constant as to make a diagnosis practically certain.

I wish now to present the salient points in a group of seven cases occurring in the form of an epidemic in one family, in which the victims followed each other to bed in rapid succession, four of whom suffered very severe and prolonged relapses. All, however, eventually made a good recovery. It is not my intention to narrate these cases as especially unique or exceptional, but as taking place under one roof and springing from one well-recognized cause: the variation in the temperature-record alone became an interesting element of study.

The fever occurred in a very healthy German family; the parents as well as the children were free from any predisposing weakness.

Case I.—Mary, æt. 13, was the first to take sick. I made my first visit to her December 6, when I obtained the following history. The patient had been complaining for nearly a week of weariness, chilliness, aching in limbs, back, and head, loss of appetite, and a general disinclination to any physical exertion. I found her at 12 M. with a temperature of 104⅘°, pulse 112, skin hot and dry, puffiness around the eyes, with an injected conjunctiva, face dark and flushed. During the day had diarrhœa with vomiting. At 8 P.M. of same day vomiting (continuing) of thick, tenacious mucus, tinged with blood and bile; bowels were opened seven times during the afternoon. Since my morning visit the girl has had low muttering delirium, but can be aroused by speaking in a loud voice. The backache was so very severe as to merit especial mention, it being more pronounced than is usually found in bad cases of typhoid. The girl constantly complained of it during the first ten days. On the same evening, at 9 P.M., the thermometer had registered 105⅘°. In the morning it was 104⅘°, in the evening it was 105°. During the day and night vomiting and purging continued nearly hourly,—fifteen times by the nurse's report.

At the end of the eighth day, the second day of my visiting, the backache continued violently, the hands being involuntarily placed in that region. Bowels continued loose, vomiting the same. Distention and tenderness of the abdomen decidedly marked, with gurgling in right iliac fossa, tongue heavily coated, dark, and foul, sordes on teeth and lips. Vomiting discontinued on third day after taking her bed. Temperature 104⅘° in the morning, 105° in the evening; low muttering delirium, alternating with violent outbursts; three or four well-defined rose-colored spots at this date made their appearance on the abdomen. After the fourth day, probably the tenth or twelfth day of her sickness, the temperature did not run higher than 104⅗°, but did not fall below 102° until the eighteenth day. One very noticeable feature in this severe case was that, for two weeks, every other morning's fall was less or intermittent in character, while the evening exacerbation remained the same. During this period there existed the wildest delirium, it being difficult at times to retain her in bed; bowels frequently moved involuntarily. The girl gained her strength very slowly; it was five weeks before the temperature approached normal, and it was ten weeks before she was able to leave her bed. She, however, made a good recovery.

The point worthy of attention is that the temperature in this nearly fatal case

remained nearly the same for the morning and the evening record. Immermann tells us that only in cases in which the fever is very severe and the absolute temperature very high is the difference less, and does not exceed three-fourths of a degree.

Case II.—The second member of the family to fall ill was the mother, æt. 32, who had acted as constant nurse to the daughter. It was thirty-four days after the daughter was taken sick, and while the daughter was yet in bed, that the mother was compelled to relinquish her duties. I might state that the mother was on the eve of her confinement, that she watched and waited on her sick child up to the hour of her illness; she passed safely through her labor, remained in bed one week, was up and around the house for *five days* before she had any decided symptoms of fever. She had a slight chill, which was soon followed by a temperature of 104⅗° in the evening. This was, however, the highest point reached. She had no delirium nor vomiting. Bowels were opened daily, but not unnatural. The temperature remained high for over one week, ranging between 103° and 104½°. It had a gradual decline for over thirty-six days, when it reached normal, without any unusual variations between the morning and evening record. Convalescence was very slow. The record was a typical temperature-record from the second week of typhoid, yet much milder than the child. The puerperal state did not seem to modify the course of the fever or endanger the life of the patient.

Case III.—The husband and father, æt. 36, a house-carpenter by trade, rugged and compactly-built German, was next on the list. He was a perfect type of physical perfection. He continued his work up to the hour of taking his bed, February 10. He had complained of a cold, headache, and sore throat for two days previously. I found him on the morning of the 10th with a temperature of 105⅗°, pulse 90, respirations 20; dry, hot skin, dark and injected countenance; bowels loose, abdomen flat; very stupid and sleepy. In this case the pulse was full and regular, never going above 90, yet for over two weeks his temperature lingered around 105°, with profound stupor alternating in the wildest delirium. He had during the second week constant *subsultus tendinum* and frequent involuntary movement of the bowels. On the twenty-second day of his illness he suffered a hemorrhage of fully eight ounces. He had several smaller hemorrhages previous to this date. On the sixteenth day his temperature fell to 101⅕°, remaining under 102° with but one exception, when it ran up to 103°. Temperature did not reach normal until the thirty-eighth day.

Case IV.—Caroline, æt. 5, was taken ill on January 13, three days after her mother. She started with a temperature of 104⅘°. She had been listless and stupid for a week preceding her complete prostration; during the prodromata I registered her temperature twice daily, but did not find the thermometer above 100°. Two days from the last date the fever had reached 105⅖°. From this point on it was a gradual decline for twelve days, when it as gradually climbed up to its old figure of 105⅖°. This intermitting type continued for forty-two days, when it fell below 100° and I ceased to make a record. The case was one of unusual severity, frequently losing large quantities of blood by the bowel, yet constipation was the rule throughout the illness. Epistaxis was also constant, the face being stained daily with blood; low delirium existed for over two weeks. The patient was in bed for over seven weeks.

Case V.—Katie, æt. 10, had a temperature-record of her own,—a marked difference existing in this case from the others: above 104⅖° to start with, reaching 105° the same evening, remaining above 104° for *three days*, then gradually declining for three days, when it assumed again the upward tendency, holding it for three days, then came a rapid fall. This intermittent character in the temperature continued for thirty-two days. This case was obstinately constipated throughout her illness, and was but slightly delirious. Recovery slow. Six weeks in bed.

Case VI.—Pauline, æt. 14, an unusually well developed girl, and the last case which I deem of sufficient interest to record in the history of this family-epidemic, will also illustrate a different phase in temperature-irregularities. Three of the children before they became actually sick were noticed to have a weary, listless expression, did not manifest interest in their play, showed a decided preference for the house, which was contrary to their usual habits.

I registered the temperature of two of the younger children for a week or more before they were stricken down, and I did not find an elevation of temperature but slightly above normal unless the temperature was taken in the evening, when it was generally near 100°. Taking into consideration the daily fluctuation in health, which is always higher in the evening, I could scarcely draw the line between the normal evening elevation in health and the insidious approach of the fever. With Pauline I still endeavored to anticipate the onset of the disease. Acting on the suggestion of some of my professional friends, I commenced to register her temperature nearly two weeks before I perceived any indications of her being the next to fall sick. I might anticipate any theoretical conclusions likely to find lodgment in your minds as to the

causation by stating that the girl had been employed in a dry-goods store, and was brought home to take charge of the sick family. Upon her devolved most of the washing and cooking for the sick. While the younger children were out of the house nearly all day at play, she was busy with household duties, and was in this way more exposed to the infectious disease than her younger sisters, who seemed to contract it so readily. I found it most convenient to take her temperature at the time I visited the other members of the family,—*i.e.*, between nine and eleven in the morning and eight and nine in the evening. I never found her temperature above normal until within four days before she was compelled to take to her bed. Three days before her prostration the thermometer registered 102°, normal the following day; second day it was 101⅘°; the following day it ran up until it reached 104⅖°. Her temperature continued high for over ten days, ranging from 103° to 105°, then assumed the intermitting character so frequently noticed in the record of the other members of this family, after which the fever-record had a gradual decline. By anticipating her attack of the fever and registering her temperature for over a week, three days in which her fever was above normal, gave us part of the ascending scale of Wunderlich, yet does not supply the gradual ascent and the lengthened arc of the semicircle which should describe the model typhoid temperature-record.

I have hinted that the cause of this epidemic had a tangible existence. While it is not the object of this paper to touch upon the etiology of typhoid, yet it may not be without interest to mention the environments of this fated household. It is unusual to have seven cases of typhoid occur in one family and follow each other in such rapid succession: yet not until the third member of the family was prostrated could an adequate cause be found.

The head of the family was an industrious carpenter, who resided, with his wife and five children (two older girls were not living at home), in a two-storied, four-roomed house near Thirteenth and Columbia Avenue. The house was quite comfortable for a small family, but not so for this one: hence they were crowded. Yet I have seen families packed in and live free from disease when there have been actually more to a room than in this family. The cellar was dry, drainage in a fair condition. A vacant lot of enclosed ground intervened between our family and the nearest neighbor on the north. This neighbor on the north was in the milk-business, and for his convenience he had excavated a pit in the vacant lot adjoining our family's cellar-wall, four feet deep, into which he had dumped the rubbish of the yard. The rain and snow falling upon the decomposing mass of organic material soon found its way through the intervening stone wall,—percolated its liquid poison into the cellar. This filth, while not at all times sufficient to be recognized by the sight, was more frequently perceptible to the sense of smell. The pit could in no way impregnate the drinking-water of the family, for as a precaution I had all the water that was consumed for that purpose brought to them from a distant neighbor.

While we have mentioned the exceptional in the temperature-record, we may also entertain a doubt of this rubbish-pit being the only factor in the family illness. The first case in the epidemic, Mary, æt. 13, was employed in a store; hence she was not in the atmosphere of the house as long as the mother, who was the only one who constantly lived in the poisoned house and yet second on the list, and, while she had a severe attack, her illness was not so prolonged as the first. Again, Pauline, the eldest girl, came from another family in perfect health, resided for three months in the infected house, exposed to every form of contagion, and was the last to succumb to the disease; and when finally she was prostrated, the fever ran a comparatively mild course.

In directing your attention especially to the peculiarities of temperature in the foregoing cases, that ended in recovery, I wish now to contrast them with one that, while the temperature was under control and lower than any of the foregoing, yet, without complications, ended fatally.

A finely-built young man of 27, regular, but rather full habit, first complained August 1 of intense headache, backache, indifferent appetite, and general disinclination to exertion. He left the city, against the wishes of friends and my advice, for a trip through the South. On the 3d he was taken violently sick; sent home, reaching the city August 4. At my first visit, same day at 12 M., temperature was 104°; at 8 P.M., 104⅖°. On the sixth day he lost consciousness. His delirium was wild and pugnacious; constant mutterings. At the same time his temperature fell below 104°, and remained below for over a week. On the tenth day his temperature reached 104⅗°. From this point it fell, and remained

under 103° until the fifteenth day, when it ran up to 104⅗° at death.

It is unusual to find patients unconscious when the temperature is so easily under control. In this patient the only antipyretic measure used was the cold bath. None of the symptoms of this case were as severe as the group occurring in the epidemic; yet this case terminated in death, while all of the others, indifferently nursed and badly surrounded, made good recoveries.

While it has been my principal object to record these cases of typhoid as departing in a measure from the temperature-law of Wunderlich, I wish to call your attention incidentally to the following facts:

1st. Six of the group of cases noticed in this paper were children, yet we had a severe course of the fever and the temperature-record commenced high, showing frequent irregularities. Wunderlich states that in children, particularly in the younger subjects, the course of typhoidal temperature is somewhat irregular. The commonest of these irregularities is its extreme mildness; yet the temperature rises in the first days to a higher average than in adults; it passes more quickly into the remitting period, and defervescence is less protracted, but complications often occur, closely indicated by the temperature.

2d. In the nine cases of typhoid, including mild as well as severe examples, we had four cases of intestinal hemorrhage, an unusually large percentage. Systematic writers on fever regard intestinal hemorrhage as a rare and grave symptom. While Liebermeister states that there is not a single symptom belonging to typhoid which can be characterized as pathognomonic, yet a tendency to diarrhœa is quite frequent and intestinal hemorrhage quite rare. In our cases we found the bowels confined in over half of the cases.

Dr. Broadbent looks upon constipation in typhoid as of sufficient importance to entitle the fever a distinct variety.

Absence of Tendon Reflexes in Diabetes.—Professor Bouchard considers this phenomenon of great importance in the prognosis of saccharine diabetes. In forty-seven cases of diabetes in which the tendon reflex persisted there were only two deaths, or one in twenty-three; in nineteen cases with absence of the reflex there were six deaths, or one in three.—*Canadian Practitioner.*

REMARKS UPON THE MANAGEMENT OF LABOR.

Read at the Philadelphia Clinical Society, Nov. 28, 1884,

BY EDWARD R. STONE, M.D.

THE remarks which I have to offer this evening are based upon one hundred cases of obstetrics attended in private practice. This number is quite too small for the deduction of any accurate statistics, and they will therefore be used simply to illustrate certain points in the management of labor. The practice of obstetrics forms a large and important part of the every-day duties of most of us, and it is well occasionally to leave the discussion of rare and difficult cases to review the common things of our art. For these reasons you will excuse the following desultory remarks, which, while they contain nothing new, may serve to introduce profitable discussion. In the beginning, let me emphasize the importance of intelligent supervision of our cases as early in pregnancy as possible, which is apt to be neglected in the exigencies of other and more pressing duties.

It is not my purpose to discuss the details of the hygiene of pregnancy, or its various complications, except to bear testimony that in primiparæ great benefit follows preparatory treatment of defective and retracted nipples. We are all painfully aware of the not uncommon sequence of imperfect and ulcerated nipples, enlarged breasts, and mammary abscess, and the books and journals direct many and various plans of treatment, the very number of which is sufficient to indicate their untrustworthiness. The primary cause of trouble is almost always that the nipples are not in condition to fulfil their function, and efforts to continue lactation make a cure very difficult. At first I was timid about disturbing the nipples during pregnancy, knowing the marked sympathy between the uterus and mammary glands, but after some experience I have always found that the pregnancy progressed without accident. In cases in which the nipples are small and retracted it is well, for several weeks before labor, to direct systematic efforts to develop them. This may be done by gentle manipulations with the hand and suction by means of a glass connected with the woman's mouth by a rubber tube (one of the common kinds of breast-pump, such as is found in every

drug-store). At the same time the cuticle should be hardened with a solution of tannin and glycerin. Other astringents are recommended, as tea, brandy, or cologne-water, but all act in a similar way. Dr. Samuel Sloan, of Glasgow, suggests that glycerin and lead should be used with the astringent, to toughen as well as harden the skin. In the interval, pressure of the clothing should be removed by wearing a nipple-shield. In my experience, depressed nipples have usually been observed in girls of stout physique whose corsets and other clothing are made to fit tightly over the breasts.* If the physician has directed that he must be called as soon as labor-pains set in, he will be able satisfactorily to practise external examination. Later on in labor, the frequently-recurring contractions will interfere with its proper fulfilment. Lusk says† "that it is a good plan to employ external palpation in every case where no opposition is made, as, even where the diagnosis by ordinary vaginal exploration is clear and indisputable, no opportunity should be lost of perfecting one's self in mapping out the fœtus through the abdominal and uterine walls. The ability not only to recognize the presenting part, but the position of the entire fœtus in the uterine cavity, is, in many cases of difficult labor, a possession of priceless value." By palpation and auscultation can be ascertained—1. The fact of pregnancy. 2. The vitality of the fœtus. 3. The probable position of the same in utero. 4. The suspicion, at least, of multiple pregnancy. By patient, firm, but gentle pressure with the hands laid flat on the abdomen, the parts of the fœtus can usually be made out with considerable accuracy. The head can be readily detected as a hard, round body, usually at the pelvic brim, while the firm resistance of the back on one side is quite different from the irregular prominences of the extremities on the other. The point of maximum intensity of the fœtal heart-sounds, which is always nearest the thorax, serves to confirm the diagnosis of position made by auscultation. In the fourth position of the vertex I have several times been able to note the unusual prominence of the extremities, and the heart-sounds far around to the right side of the mother. A case which occurred some years ago, and in which Dr. J. B. Walker was called to my assistance, well illustrates the disastrous result of not recognizing a twin-pregnancy, which might have been done if external diagnosis had been practised.

Mrs. M., a slender Irishwoman, of medium height, æt. 38, was taken in labor at the termination of the sixth pregnancy. Nothing unusual was noticed, except that the uterus was very prominent. No external examination was made. The presentation was the vertex in the first position, and the cervix was soft and dilatable, the os about two-thirds dilated. The pains, however, were weak and ineffective. After waiting about two hours without much progress, I desired to use the forceps, but was not permitted to do so. Thinking that it was a proper case for the use of ergot as a uterine stimulant, two small doses were given with an interval of half an hour. The pains then became efficient, and a male child of rather small size (six and a half pounds) was expelled. As the birth was taking place it was ascertained that the womb contained another fœtus, whose head could be felt in the right iliac fossa, and under the ergotized contractions the shoulder was forced down in spite of efforts to prevent it. The uterus continued to act violently, and the fœtus perished before an anæsthetic could be administered for the purpose of version. As we were preparing for that operation, the fœtus was suddenly delivered, probably by a process of spontaneous version.

This case reflects no credit upon the practitioner, but is none the less instructive, not only as showing the importance of using every means of diagnosis at our command in every case, but also as pointing a moral in regard to ergot, which has since deterred me from its use in similar circumstances. It is admitted that the diagnosis of twins before the birth of the first is difficult, and in some cases impossible, but in this case a careful examination would, I am sure, have disclosed enough to save me from the fatal error of administering ergot and thereby destroying the life of the second fœtus.

This was the only case of multiple pregnancy which I have met with, and I have not therefore had an opportunity of testing the value of external diagnosis. The points in diagnosis of twin-pregnancy, as

* One may well wonder, also, whether the pernicious habit of ignorant nurses of rudely squeezing the breasts of newborn female infants may not have a bad effect upon the future usefulness of the glands. In two cases I have seen abscess result from this barbarous practice, and it is reasonable to suppose that the results of such abuse may leave the gland in a permanently crippled condition. If the mammary glands of an infant become swollen, it is well to forestall malpractice by covering them with small belladonna plasters, which will also allow nature to remove the trifling difficulty.

† Op. cit., p. 203.

given by Cazeaux, Lusk, Playfair, and others, are unusual size of abdominal tumor, a longitudinal depression in the median line, the detection of duplicate heads and other parts, and heart-sounds at two remote points of intensity. The difficulties in the way of external diagnosis are obesity of the mother, excess of the amniotic fluid, and contraction of the abdominal muscles due to the nervousness or timidity of the patient. The last, however, may be overcome with patience and tact on the part of the physician.

In the first stage of labor, the ordinary difficulty, in primiparæ at least, is from a lack of the proper dilatability of the cervix, the degree of rigidity varying from a mere temporary retardation of labor to those difficult cases which are only overcome by mechanical dilatation. In my cases, which show a rather large percentage of primiparæ (thirty per cent.), there were several requiring assistance, but none of a serious character. At first careful and systematic trial was made of the warm-water douche, but the results were disappointing, as it only washed away the secretions which nature throws out to lubricate the parts, and had no marked effect in relaxing the os. Chloral given in fifteen-grain doses until three or four doses were taken had, however, a most happy effect, especially where the rigidity was associated with marked suffering in an oversensitive cervix. In two cases, after the ordinary means had failed and the patient's nervous system was suffering from protracted anguish, a full dose of morphia hypodermically caused a temporary cessation of labor, which, after a refreshing sleep, was resumed and successfully terminated. In four cases, however, laceration of the cervix occurred sufficient to cause the usual symptoms subsequently. There may have been others, but these were all which were brought to my notice. Examination of some of these cases of imperfect dilatation has led me to believe that the maximum limit of normal expansion of the os may be insufficient to allow the head to pass, when a laceration is unavoidable, just as the vulvar orifice may be too small to give exit to the head without injury.

The proper management of the perineum occupies the anxious care of all obstetricians, and it seems that, even with the best-known methods, we have yet much to learn. It is well that the old plan of pressure with a folded napkin is about obsolete, as it was erroneous in theory, and useless, if not harmful, in practice. The method of Professor Goodell accomplishes perhaps better than any other the three indications,—viz., to retard delivery, to assist extension, and, by drawing forward the perineum, prevent it from suddenly slipping back over the brow. It has seemed to me, however, open to the objection that in some cases the fingers in the rectum increase the tenesmic efforts and compel the patient to bear down more than is proper and safe. After having had a patient draw suddenly away from my hand at a critical period, I have, in some cases, adopted Dr. Jas. D. McGaughey's* plan of assisting extension and retarding delivery with the left hand passed between the woman's thighs from above. This can be done by having the patient on the usual left side near the edge of the bed, with the thighs separated, while the physician sits behind the patient, facing the foot of the bed. It has seemed to me that in this way the advancing head can be easier controlled, and the arm across the woman prevents any sudden and hazardous movements. The right hand is free to draw forward the perineum or to reinforce it in any other way. It has been my misfortune to meet with seven cases of rupture, all primiparæ; six of these were of moderate extent, not involving the sphincter ani. In one case the rent involved the rectum. It was, briefly, as follows:

Mrs. L., æt. 22, primipara, taken in labor about midnight, but was not visited until about 10 A.M. next day. The fœtal head was found to be well down in the cavity of the pelvis, the vertex presenting towards the sacrum. The pains were severe, but nature was evidently unequal to the task. Ether was administered and forceps applied. After considerable effort, delivery was effected by bringing the head into forced flexion. The perineum was torn through the sphincter ani, but primary union followed the introduction of sutures.

There is still diversity of opinion as to what constitutes a laceration calling for the use of sutures, physicians of considerable experience stating that they never had a case requiring other treatment than

* Am. Jour. of Obstetrics, June, 1884.

bandaging the knees together, while others often find use for sutures. The only safe rule is to make a careful examination of the parts, and if the muscular tissues and central tendon of the perineum are divided it is useless, in my opinion, to look for primary union unless the wound is firmly united. The legs may be tied, but the retraction of the transverse perineal muscles will cause the wound to gape.

The proper treatment of the third stage is of the greatest importance, but the history of the subject, unfortunately, teaches that the most diverse plans, from rude and forcible delivery to an expectant plan carried to an almost ridiculous extent, have had their advocates in high places. Not many years ago the teaching was to wait a half-hour, and gently assist nature by drawing on the cord; then came Crédé, with his many disciples of expression, and for several years this method has been the most popular. Quite lately, however, the pendulum of medical opinion has shown signs of swinging back again to less active means. Several have expressed themselves as being dissatisfied with Crédé's plan, because it empties the womb too speedily and is apt to leave behind the membranes to become a source of danger from hemorrhage and septicæmia. These either place themselves in an attitude of "armed neutrality" and wait for nature to accomplish the object, or adopt an intermediate plan which has received the name and sanction of the Dublin school. The latter is described* as following down the uterus with the hand as a sentinel and guard, and, as soon as uterine contractions are pronounced, assisting by firmer pressure.

Professor Stadfelt, of Copenhagen, presented to the late International Congress the results of the respective methods in a large number of cases. His conclusions were that Crédé's method is preferable to the expectant. Detachment and retention of membranes occurred somewhat more frequently after expression, but he thought that the objectors to it attached too much importance to the objections, and overlooked the fact that it removed dangers attendant on the time of waiting in the expectant plan. The cases treated by Crédé's method also showed a less per cent. of mortality and puerperal disease than did those treated expectantly. All will admit that the patient is not safe until the placenta is expelled, which is sufficient ground for its speedy removal, if that can be accomplished safely. In the majority of cases the placenta will be found to be wholly detached very soon after, if not simultaneously with, the expulsion of the fœtus, and can no longer serve any useful purpose, except to provoke uterine contractions to expel it. If the uterus has been followed down with the hand, there does not seem to be any good reason for not removing it as soon as the contractions are resumed and the blood in the uterine sinuses has had time to coagulate.

Dr. J. C. Reeve, in an historical and critical article upon the management of the placenta, expresses the opinion that Crédé wrote his own condemnation with the statement that in his practice the average duration of the third stage was only ten minutes. But it should not be forgotten that Crédé advised that the placenta should not be expressed until the uterine contractions are re-established, and this appears to me to do away with the objection that the method empties the womb too speedily.

It has been my custom to keep the hand upon the uterus from the time of the delivery of the shoulders until the third stage is completed, and for several minutes after, and as soon as a firm contraction is felt to remove the placenta by pressing and compressing the uterus with the left hand, while two fingers of the right hand are hooked into the edge of the after-birth which is usually protruding from the os, making traction and twisting up the membranes as soon as the placenta is brought outside of the vulva. Thus the left hand is assisted in the extraction, and the membranes are not liable to become detached, as sometimes happens with unassisted expression. I have been in the habit of administering a full dose of ergot as the head is emerging, in all cases other than primiparæ. This practice is condemned by Lusk, Playfair, and others, on the ground that the contractions produced by the drug may imprison the placenta and lead to difficulty in its removal. This objection no doubt applies to those cases in which ergot is administered and the expectant plan pursued, but not if the after-birth is removed as soon as the pains are re-established. We are told by Playfair, and Wood in his Therapeutics, that the drug requires fifteen to

* Med. News, Oct. 4, 1884.

twenty minutes in which to act, which gives ample time for its removal by Crédé's method or some modification of it. It is this tardiness of action which has influenced me in administering it early to forestall a possible flooding, for the patient may die exsanguine before the ecbolic action of the drug can be secured. In my cases there was neither a single case of hemorrhage from inertia nor imprisonment of the placenta. Those who object to giving ergot before the completion of the third stage should be prepared to administer it hypodermically if symptoms of inertia come on.

The administration of ergot also has a favorable effect on the after-pains, by keeping the womb contracted, and gives the latter a start towards healthy involution.

The use of anæsthetics in obstetric practice is, perhaps, not as common in this country as it should be. This may be partly due to the national antipathy to chloroform, and the fact that ether is bulky, disagreeable, and liable to cause intoxication, during which the patient is difficult to control. Last winter Dr. E. E. Montgomery suggested to me the use of bromide of ethyl, and I have since administered it in eight cases, always with the very best results. The remedy certainly deserves a more extended trial, and I would commend its use to those engaged in the practice of obstetrics. Its advantages are—the small amount required to relieve pain; it does not interfere with muscular contractions, either voluntary or of the uterus; it does not seem to have a dangerous effect upon the heart, or to lead afterwards to uterine inertia.

In these days of bacilli and other microscopic germs of disease, obstetrics naturally comes in for its share of antiseptic treatment. The heads of the various great lying-in establishments have given us the details of carbolized hip-baths, removal of hair from the genitals, rubber gloves, antiseptic vaginal and uterine injections, and other means of excluding possible germs of disease, and some have gone so far as to accuse those who do not as they direct of culpable negligence. But it is well to remember that those to whom we look for instruction usually gather their large experience in maternities whose proximity to general hospitals provides a constant and fruitful source of septicæmia. Blockley Hospital is one of these, and I have seen the time when scarcely a single woman delivered in that institution presented a normal puerperal period. But these precautions surely do not apply to private practice, if the practitioner is careful not to be a carrier of the germs of scarlet fever, erysipelas, or other similar disease. In attending considerably more than one hundred cases, I have yet to see a single case of septicæmia, although no other precaution than ordinary cleanliness was observed. In one hundred cases the mortality has been nothing, and the percentage of disease nine per cent. Three of these were mild cellulitis apparently due to lacerated cervix; one was a severe case of the same disease, which progressed to the formation of abscess. Recovery took place slowly, leaving the uterus fixed in the pelvis, but the woman after several months was able to work, and has fair health. The other cases, five in number, were mammary inflammation and abscess. This list does not include, however, abortions, nor deliveries before the fœtus was viable.

REPORT ON MEDICAL CHEMISTRY.

BY WILLIAM H. GREENE, M.D.

A New Levogyrate Acid in Diabetic Urine, Pseudo-Oxybutyric Acid.—E. Külz and Hass, some time since, have shown that normal human urine rotates the plane of polarized light to the left, and that the left-handed rotation is still more marked with the urine of cattle, horses, and pigs. The rotatory power is diminished after treatment with lead acetate, but increased by lead acetate and ammonia. Külz now finds that in severe cases of diabetes the urine possesses levogyrate properties which remain after treatment with lead acetate and ammonia, and which cannot be attributed to any of the hitherto known constituents of the urine. This he ascribes to an acid having the composition of oxybutyric acid ($C^4H^8O^3$), and which he isolates by the following process. The glucose is first destroyed by fermentation, and the urine concentrated to a small bulk and precipitated with neutral lead acetate and basic lead acetate and ammonia; the filtrate is freed from lead and evaporated to a syrupy con-

sistence. It is then treated with a little ninety-five-per-cent. alcohol, afterwards with absolute alcohol, and allowed to stand twenty-four hours. The clear decanted solution is then mixed with about five times its volume of ether, which precipitates the greater part of the new acid. The barium salt is soluble in alcohol, and may serve for the preparation of other salts which separate from their alcoholic solutions on the addition of ether. Analysis of the salts and of the free acid, which may be obtained in syrupy form by desiccation over sulphuric acid, gave figures corresponding closely with the formula of an oxybutyric acid, but the properties of the new acid do not correspond with those of either of the four known acids having that composition. It produces no color with ferric chloride, and does not volatilize in a current of steam. Külz has named it pseudo-oxybutyric acid, and has demonstrated its existence in the urine of all severe cases of diabetes where the presence of acetylacetic acid occasions the production of a Burgundy-red color on the addition of ferric chloride. The so-called *acetonuria* is possibly accounted for by the presence of this acid, which, according to Külz, yields acetone when oxidized by potassium dichromate and sulphuric acid, and is itself probably a normal oxidation-product of glucose. Also, the presence of this acid would explain the fact that the polarimetric estimation of glucose in urine often gives results considerably lower than those found by the use of Fehling's solution. If, after the fermentation of the glucose, a sample of urine is levogyrate, the reading to the left should be added to that previously found to the right.

O. Minkowski has continued his researches on the presence of oxybutyric acid in the urine of diabetes,* and has succeeded in further purifying the acid and preparing certain of its salts. He has also investigated its optical properties, and finds for the free acid a rotation of $(\alpha)_D = -20.6°$; for the silver salt, $-10.1°$. Külz found for the silver salt of his acid above described $(\alpha)_j = -8.637°$. Throwing aside its optical properties, Minkowski's acid closely resembles β-oxybutyric acid, and this investigator proposes to call it *acetonic acid*. In all respects it corresponds to the pseudo-oxybutyric acid of Külz, and the two are undoubtedly identical.

Minkowski also considers that the acetylacetic acid obtained from urine by Jaksch was probably an oxybutyric acid. However this may be, it appears certain that the substances obtained by Stadelmann, Külz, and Minkowski are identical with each other, and have the composition of an oxybutyric acid, and that this acid is very frequently if not constantly present in the urine in grave cases of diabetes.

Minkowski believes, with Stadelmann, that diabetic coma is due not to the action of any specific basic substance, but to the accumulation of acids in the organism; Walter and Von Frerichs have energetically combated this opinion.

Some New Applications of Weyl's Creatinine Reaction. Acetonuria.—The evanescent red color produced by the addition of solution of sodium nitroferrocyanide and sodium hydrate to solutions containing creatinine is usually known as Weyl's reaction. E. Legal finds that acetone and acetylacetic acid respond to the reagents just as does creatinine, with the difference that the brown-red color fades much more slowly and becomes darker on the addition of acetic acid, while it appears carmine-red when diluted. Diabetic urine which produces a red color with ferric chloride gives the same reaction, but ethyldiacetic acid behaves differently: its solution becomes brown-yellow when treated with the above reagents and acidulated with acetic acid, and is then straw-yellow when diluted. Legal claims to have detected acetone in the distillate of normal urine treated in this manner, and it would follow that, in the application of the test for determining the presence of creatinine, the urine should first be boiled.

C. Le Nobel has independently made an observation similar to the above. He finds that the ruby-red color produced by sodium nitroferrocyanide and strong sodium hydrate in solutions containing acetone is changed to violet by the addition of glacial acetic acid, and becomes green-blue when the solution is boiled or after it has been allowed to stand. Glacial acetic acid changes the color of the creatinine reaction to green. With ammonia and sodium nitroferrocyanide, acetone gives first a rose-red, then a violet or wine color;

* See Medical Times, vol. xiv. page 708, and vol. xv. page 123.

heat deepens the color, and boiling with acid changes it to green-blue.

As additional characters which may assist in the detection of acetone, Le Nobel cites its reaction with tincture of iodine and ammonia; one-ten-thousandth of a milligramme of acetone then betrays its presence by the production of iodoform, while under the same circumstances alcohol gives no results. Also, the one-hundredth of a milligramme of acetone may be detected by its power of dissolving mercuric oxide. In this test a solution of mercuric chloride is precipitated by the addition of alcoholic potassium hydrate, and then agitated with the liquid supposed to contain acetone; the mixture is filtered, and the filtrate tested for mercury with ammonium sulphide. Lead hydrate also dissolves in acetone in the absence of alkaline hydrates.

Ethyldiacetic acid gives no iodoform reaction, and behaves somewhat differently from acetone when subjected to Weyl's reaction. Mercuric oxide and lead hydrate are dissolved by ethyldiacetic acid. This acid distils without decomposition when its solution is boiled, and it is undecomposed by organic and dilute mineral acids; it is, however, decomposed by strong mineral acids, especially by the aid of heat.

Aldehyde simulates creatinine in Weyl's reaction still more closely than either of the other two bodies mentioned.

Le Nobel criticises Von Jaksch's method for the estimation of acetone, and considers that, even if acetone be constantly present in cases of acetonuria, its quantity is quite insignificant, but appears to increase after the ingestion of alcohol or sugar.

Normal urine contains still another substance which gives the iodoform reaction. In fever there is often decided acetonuria, so that acetone can be recognized in the distillate from five hundred cubic centimetres of urine; but the production of acetone is not dependent on the fever intensity, being greater when there is a large amount of indican present. Diabetic coma does not appear to depend on acetonuria, and an increased proportion of acetone in the urine is not to be regarded as an alarming symptom. The red-brown reaction of urine with ferric chloride does not depend on the presence of ethyldiacetic acid, and Le Nobel considers it a doubtful question whether it is always due to acetylacetic acid, as held by Von Jaksch.

It may also be mentioned that Le Nobel claims to have found ethyl alcohol and acetone (possibly ethyl-acetic acid) in the breath exhaled by diabetics.

E. Salkowski reclaims priority for Legal's and Le Nobel's modification of Weyl's reaction, and states that Le Nobel is wrong in asserting that the creatinine reaction does not give a blue color on boiling in the presence of acetic acid.

For the Estimation of Nitrogen in urine and excrements, W. Camerer places the substance to be analyzed in a glass tube sealed with paraffin. This is then inserted in a long combustion-tube with soda lime, and the analysis is conducted in the usual manner. Camerer finds that the nitrogen in fæces must be estimated in fresh material: drying at a temperature of 100°–105° C. occasioned a loss of 0.109 gramme of nitrogen for 100 grammes of fresh fæces, or 8.2 per cent. of the total nitrogen present. The estimation of nitrogen in urine by the hypobromite method gave, in comparison with a similar estimation by combustion with soda lime, a loss of 10.9 per cent.

The Relation between the Elimination of Phosphoric Acid and that of Nitrogen in the Urine during Alimentation by Brain-Substance has been investigated by G. Politis. The proportion of phosphorus in brain-tissue is known to be higher than in other animal tissues, and the author has found in fresh ox-brain 0.81 per cent. of P^2O^5 for 1.69 to 1.78 per cent. of nitrogen. In one experiment a dog was fed on bones for one day, then for three days exclusively on ox-brains, and on the fifth day again on bones. The ratio between the P^2O^5 and nitrogen eliminated in the urine on those days was found to be 1 : 5.02, 3.2, 2.2, 2.0, 2.2, and the curves representing the daily excretion of phosphorus and of nitrogen were sensibly parallel. During an exclusive flesh-diet Feder found a much more rapid elimination of phosphoric acid in the urine, and Politis explains this by the fact that the phosphorus in flesh exists in the form of phosphates, while that in brain-substance is in the form of complex ethers, such as lecithin. The latter is absorbed with difficulty, and during nutrition with brain-substance the author has found it in the

fæces, together with a very small quantity of glycerin-phosphoric acid. Bokay found no lecithin in the fæces during a diet of yolk of egg. In another experiment of Politis a dog was fed exclusively on flesh, and the ratio of the phosphoric anhydride to the nitrogen in the urine was found to be 1 : 6.7; when the diet was fifty parts of brain-substance to one of flesh, both nitrogen and phosphoric acid increased in the urine without the proportion between them sensibly varying: hence the before-observed variations in this proportion cannot with any probability be attributed to the influence of the ingested brain-substance.

It is to be remembered that Gamgee, Paton, Cazeneuve, and Lépine could detect no increase in the elimination of phosphoric acid in the urine after mental work. The diminution in the excretion of phosphoric acid observed by B. Schulze after the internal administration of potassium bromide is due, according to Politis, to a retention of phosphoric acid in the blood, this retention depending on a double decomposition between the potassium bromide and the sodium phosphate.

The Influence of Water on the Estimation of Urea by Liebig's Method. —Luzzatto has again studied the effect of dilution on the final reaction in Liebig's method, which, it is well known, requires for dilute urea solutions a larger quantity of the mercuric nitrate solution, and for concentrated solutions a smaller quantity than normal. As Pflüger had already recommended, Luzzatto, in a recent communication, counsels that the final reaction with sodium carbonate should be made in the entire bulk of liquid, especially when this bulk is small.

Kairin (oxyhydrethylchinolin), according to Petri and Lehmann, occurs as a salt of sulphuric acid in the urine in phthisis. The compound is not destroyed by the ammoniacal fermentation of urine, but is decomposed by long boiling with hydrochloric acid. In dilute acetic acid solution it gives a fuchsin-red color on the addition of a little chlorinated lime solution, but the color appears only in about half an hour. The spectrum of the solution shows an absorption band between D½ E and F. Kairin itself gives, under these circumstances, a different red, which soon changes to dark-brown with a faint violet reflection.

REMOVAL OF UTERUS AND OVARIES BY ABDOMINAL SECTION FOR FIBRO-MYOMATA — DEATH ON TWELFTH DAY, FROM SEPTICÆMIA.

Read before the Philadelphia County Medical Society, December 17, 1884,

BY J. M. BARTON, M.D.

MRS. K., æt. 31 years, was brought to me last September by Dr. M. B. Dwight, of Jersey Shore, Pennsylvania. She was very pale, the face and lips being entirely colorless: indeed, the appearance of the patient suggested the presence of malignant disease. She had been losing more blood at her menstrual periods than she should, for several years, and for several months she had a daily loss, frequently in quite large amounts. She was losing strength rapidly, and had to be carried to her room on her arrival in this city.

On examination, a large, hard, smooth, and freely-movable tumor, evidently the uterus, extending three inches above the umbilicus, was found; by the sound, Dr. Dwight's diagnosis of a submucous fibroid with extensive uterine attachments was readily confirmed.

As the uterus was entirely out of the pelvis, as the attachments of the tumor occupied more than three-fourths of its entire circumference, and as the remaining uterine wall was much thinned, removal by the vagina was plainly impossible. I advised extirpation of the ovaries, if accessible, or of the entire uterus, if, on exploration, it appeared preferable.

The patient returned to her home, as she preferred to have the operation performed there, to which I agreed, as I considered the mountain air much more favorable for operation and after-treatment than the wards of a general hospital.

On September 30 I visited Jersey Shore and removed the growth, assisted by Drs. Dwight and Cline, of that place, Drs. Detweiler and Youngman, of Williamsport, Dr. Armstrong, of Lock Haven, and Dr. Orville Horwitz, of Philadelphia.

Thorough antiseptic precautions were taken: the hands of the operator and assistants were washed in carbolic acid solution; all the instruments and ligatures were immersed in a similar mixture; the sponges were washed in a warm solution of the same acid; the abdomen of the patient was washed first with turpentine,

then with soap and water, and lastly with carbolic acid solution.

I made a vertical incision through the abdominal wall, midway between the umbilicus and pubes, about two and a half inches long, through which I readily drew the right ovary; the left, however, could not be reached. Finding the uterus free from adhesions, we decided to remove it. I increased the incision until it ran nearly from ensiform cartilage to pubes, carefully checking all hemorrhage by forceps and catgut ligatures before opening the peritoneum; the uterus was readily lifted from its bed and placed upright; the left broad ligament was attached posteriorly and the left ovary lay against the spine, showing that it could not have been reached through the original incision. The intestines were held away from the uterus and supported by large flat sponges wrung out of warm carbolic acid solution. The broad ligaments were tied in sections with carbolized silk, and Thomas's large clamp placed upon the neck of the uterus.

Surrounding the parts with sponges to prevent blood from entering the peritoneal cavity, into which so far none had flowed, the uterus and both ovaries were rapidly removed. There being but little tension on the pedicle, we decided to treat it outside.

The stump was trimmed so as to leave but little projecting above the clamp; it was transfixed by a large pin, and was seared on its cut surface by the actual cautery; the wound was closed by the interrupted suture introduced from within in the usual manner. It was not found necessary to make the "toilet of the peritoneum," as, thanks to the care of my assistants, no blood had been allowed to enter that cavity, and, indeed, but little was lost during the entire operation.

The uterus was seven inches in diameter and nearly a sphere; it was occupied by a single fibro-myoma, which was attached to the entire uterine walls, with the exception of a narrow channel about two inches wide, running from neck to fundus. On section, it presented the usual appearance of such growths, except in its centre, where it appeared to have undergone sarcomatous degeneration. This suspicion was subsequently confirmed on microscopical examination.

The after-treatment of the case was in the hands of Dr. Dwight, from whose very complete notes I take the following points:

On the evening of the operation, the temperature rose to 102.5°, the pulse to 120; under opium suppositories and occasional hypodermics of morphia the patient was quite comfortable; she took nothing whatever into the stomach except small quantities of hot water, and had no vomiting.

On the second day the thermometer rose to 104°, the maximum temperature observed.

On the third day she took some barley-water, and in the evening some beef-tea, the general condition being improved and improving still more on the fourth day.

On the fifth day (October 4) the bowels were moved by an enema; opium stopped; beef-tea, brandy, and warm milk were taken freely; the patient was quite comfortable.

On the sixth day (October 5) patient rested well during the night; takes warm milk every three hours; pulse stronger, 120; temperature, 101°. Patient looks quite bright; natural movement of the bowels.

The notes of the seventh, eighth, and ninth days are almost identical with the last one read, except that the stitches were removed, and on the ninth day there was considerable pus coming from the wound, and some swelling of the right parotid gland.

On the tenth day the swelling of the parotid gland increased, there were evidences of systemic poisoning, and on the evening of the eleventh day she died.

At the autopsy, there was no inflammation of intestine; there was no pus found in lungs, liver, or kidneys, though there was some in the abdominal cavity. This had probably entered a day or two before her death, and from it arose the blood-poisoning, which proved fatal.

INDIGO-FORMING SUBSTANCES IN THE URINE.—J. Hoppe-Seyler (*Zeitschrift für Physiol. Chem.*, Band viii.) obtained one gramme of crystallized indican from twenty-five litres of normal dogs' urine, in which it exists in sufficient quantity to be detected by Jaffe's reaction. To determine if indican undergo any change in the organism, 2.7 grammes were injected into an animal, but in the urine indican only was found. No increase was caused in its elimination by the injection of orthonitrocinnamic acid, or of orthonitrobenzaldehyde alone, or together with aceton.—*London Medical Record.*

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

CLINICAL SERVICE OF THOS. G. MORTON, M.D.,

One of the Attending Surgeons to the Hospital.

Lecture delivered November 29, 1884.

A CASE OF COMPOUND, COMPLICATED, COMMINUTED FRACTURE OF THE HUMERUS.

GENTLEMEN,—The first case that I will present this morning is one of a sailor, 54 years of age, who has sustained a compound complicated fracture of the lower third of the humerus by a fall on board ship two weeks ago. It is compound, because the fractured ends of the bone can be felt in the open wound; complicated, because the injury extends into the joint. A compound fracture is not necessarily a complicated fracture, even when, as in this case, it is at the same time comminuted. A fracture becomes complicated in a surgical sense when it is attended by injury of important structures, such as large blood-vessels or nerve-trunks, or when it extends into a joint. The fracture may, therefore, be complicated without being compound or comminuted.

Such injuries as the one before us are generally grave in proportion to their extent, or to the involvement of the joint surface. Immediately following such an injury, the synovial membrane lining the joint (which in health secretes simply enough fluid to lubricate the articulation) becomes inflamed, and effusion follows. The injury, frequently, is also sufficiently great to cause contusion of some adjacent structures, followed by more or less inflammation. The result is inflammation of the synovial membrane, or synovitis, and changes in its structure, which, with the fracture, leads to permanent alteration in the joint. Where the force has been sufficiently great to produce a compound fracture, there is usually severe inflammation. In either case the changes occurring in the synovial membrane are the same as those in hip-joint disease, or white swelling, the inflammation in one case being traumatic, in the other the result of constitutional disease.

Now, the chief danger from the accident which this elbow-joint has sustained does not consist simply in the fracture of the bone, but in the amount of injury to which adjacent structures have been subjected. If it were simply a fracture of the bone, we might have repair without marked degree of inflammation; but, where there is so much laceration, repair must take place by inflammation, which often results in abscess. This is what occurred here. I was obliged to make free incisions on the back of the arm to give vent to serum and pus. If you notice here, you will see a slight blush of inflammation upon the radial aspect of the arm, where there is another subcutaneous collection, which is either an abscess or a mass of broken-down and partially-decomposed blood.

In the prognosis of such injuries two things must especially be kept in mind,—the nature and the location of the lesion. The prognosis also varies with the age. A child with a compound fracture of the elbow—say a boy of 12 years of age—will give much better results from the treatment than a man of 50. One reason is that the reparative processes are more active in a child, on account of its growing condition; another is that these fractures in adult life usually occur in laboring-men who are given to the excessive use of alcohol, and their vital powers are impaired by their mode of life. In a child we are often able to seal up the surface-wound and to convert the case at once into one of simple fracture; this can only rarely be done successfully with adults. Every year of life reduces the chances of recovery with subsequent usefulness of the joint.

In cases of fracture involving a joint the prognosis varies with the importance of the joint and its size. It is worse in a hinge-joint like the elbow. You know that a hinge that is clogged by paint or any foreign substance cannot work smoothly. So in this joint, as a result of the fracture and changes in the synovial membrane, there will be more or less anchylosis, depending upon the plastic exudation and the inflammatory changes in the bones and membranes.

The effects of such injury may be inferred from this dry specimen from the museum of the hospital, illustrating a compound fracture of the lower end of the humerus extending through the condyles and involving the joint; the shaft above is broken in a transverse direction.

As regards the diagnosis, the symptoms

of such fractures are generally so well marked that if the surgeon see the case immediately after the injury there can be no mistake in the opinion he forms of the fracture; seen later, there may be so much swelling as to interfere with the diagnosis. In all cases where the nature of the case is not plain, it is better to give ether and carefully examine the injury. The joint may be invaded by a fracture from any direction; very often there is also luxation, due to the separation of the condyles. The bones of the forearm may be forced up so violently as to separate the fragments of the humerus, causing a luxation backwards. When the fracture is compound you can readily detect the fracture by inserting the finger if the wound be a large one.

Some of the most difficult of these cases of injury around the elbow-joint are those of fractures involving the head of the radius; sometimes it is almost impossible, even with the aid of ether, to make out the exact line of separation of the fragments.

With reference to treatment I will say a few words. In the first place, it is always proper to try to convert a compound into the simple variety of fracture by hermetically sealing it at once with lint and the compound tincture of benzoin, and covering the wounded part with a solution of laudanum and lead-water. It also is advisable to elevate the limb, and to give the patient anodynes. If you cannot convert it into a simple fracture, you must prepare yourself for what is likely to occur after compound fracture,—cellulitis and abscess. This is what has occurred in the patient before you. Sometimes the appearances are those of erysipelas, which you should also be prepared for. Where abscess forms, it must be evacuated early, in order to relieve the part from the irritation of the purulent material.

It is always well to bear well in mind the anatomical relations in making your incisions. You know that the principal blood-vessels and nerve-trunks lie upon the inner and anterior aspect of the limb, placed there because they are in this position less liable to injury. There is nothing, therefore, to make you fear long or deep incisions in the outer aspect of the arm. Here I make an incision at least five inches upon the arm and forearm, which gives free vent to the pus. This abscess seems to have been consequent upon injury received by the soft parts at the time of the injury; I cannot perceive any connection between the abscess and the fractured joint with my finger. It is an excellent plan after etherizing the patient to use the finger as a probe, so as to establish more accurately the limits of an injury.

When he was admitted there was a large amount of swelling, and the patient refused at that time to take ether to permit a careful examination. I now find a large portion of the upper fragment of the humerus denuded of periosteum. I will extend the wound through the triceps muscle, in order to make the bone project. Having exposed it, I now remove about three inches of it with the saw, and pack the wound with carbolized lint, and apply a posterior right-angled splint. It is a case in which amputation will probably be necessary.

[At the next clinic amputation of the arm at the middle was performed. The patient afterwards made a good recovery. —Rep.]

EXTENSIVE KELOID, PRODUCING GREAT DISFIGUREMENT OF THE FACE AND NECK.

This colored man, 32 years of age, was engaged in the working of a cotton-press eighteen months ago, when he was so unfortunate as to be severely burned in his hands and face and upper portion of

his breast and shoulders by an explosion. The burns healed well, but, as you see, the cicatrices have taken on keloid growth, which has involved in a mass of new growth the neck, both auricles, and the sides of his face, producing great disfigure-

ment, interfering with movement of the jaw and with hearing. We have applied collodion to the growth, and it has apparently led to some contraction, but probably no more than any dressing would which exercised pressure. We would probably have had just as good results from an ordinary bandage.

I propose this morning to amputate a portion of this tissue, in the hope that a healthy scar may be obtained, such as you see in his hands. I will remove the mass surrounding the right side of the face, as the growth here interferes with his hearing. I can save part of the pinna of the ear.

[This operation was performed without much bleeding. Two weeks later the wound had nearly closed, and the patient was willing to have the other ear operated upon. This was performed Saturday, December 20. The growth, which covered both ears, the sides of the face, and the neck, was successfully excised.—Rep.]

TRANSLATIONS.

Treatment of Acute Pneumonia by Baths.—If pneumonia be caused by the development in the human body of a specific microbe, as Dr. Chaumier (*Congrès de Blois*) maintained in a former communication, he insists that more account should be taken of this important etiological discovery as a basis for treatment. We should not, he says, add to the poison in the system another which is able to cause death as well as the first; and he unsparingly condemns venesection and blisters on account of their debilitating effects. Statistics prove that pneumonia abandoned to itself pursues a more favorable course than when treated by emetics, bleeding, and blisters. Although the disease cannot be cured, much can be done to relieve the symptoms, especially by cold baths. Each bath, at a temperature of 28° to 32° Cent. (82° to 90° Fahr.), was at once followed, in his experience, by an amelioration of the symptoms, lasting two or three hours. Two or three such baths were given daily. The author gives the following conclusions, based upon fifteen cases (fourteen were children), of which all recovered:

1. Cold baths do not present any danger in pneumonia at any period at which they may be employed.

2. They reduce the temperature and the frequency of the pulse, lead to the disappearance of the *bruits de souffle* caused by the fever; they diminish also the dyspnœa considerably; they relieve the thirst and permit a more abundant alimentation.

3. Having only used the bath with those who recovered without other treatment, M. Chaumier maintains a sage reserve as to the results to be expected from the treatment: he does not assert that these baths diminish the mortality, although everything leads him to believe that they do.

4. In adults, in order to obtain a durable amelioration, a bath should be given every two or three hours.—*Revue de Thérapeutique Médico-Chirurgicale.*

[Baths at the temperature indicated would not usually be considered as cold baths, but for pneumonia they are certainly preferable to cold baths as generally understood.—Ed. P. M. T.]

Incompatibility of Quinine and Iodide of Potassium.—M. Rabuteau, having seen gastric disorder, anxiety, nervousness, and general malaise follow the simultaneous administration of iodide of potassium and sulphate of quinine, attributes the symptoms to the chemical reaction, with local irritation of the stomach by the nascent iodine. He also warns against the administration of quinine to a menstruating patient, as serious and even fatal symptoms may ensue.—*Gazette des Hôpitaux.*

Morbus Maculosis Weilhofii.—Dr. Th. Hryntschak, of Vienna, publishes in the *Arch. f. Kinderheilk.* some experiments carried on with a view of deciding the question as to the contagiousness of morbus maculosis Weilhofii. He was not able to verify the results obtained by Petrone, inasmuch as the rabbits which he experimented upon did not suffer from the disease either when vaccinated directly or with the culture-fluids.

Oleum Gaultheriæ in Acute Rheumatism.—At the clinic of Professor Rossbach oil of gaultheria has been employed in a large series of cases of acute articular rheumatism, followed by equally prompt and striking results as had been obtained previously from the salicylate of soda. It is recommended to give it in capsule, after eating, on account of its disturbing effect upon digestion.—*Correspondenz-Blatt der Allgem. Aerzt. Ver. von Thüringen.*

EDITORIAL.

THE COAGULATION OF THE BLOOD.

AN able and interesting review of the various theories which have been prominently upheld of late years concerning the coagulation of the blood is contained in a paper by Frederick P. Henry in the *Archives of Medicine*.* After premising the statement that coagulation is always a pathological process and never physiological, and referring to the extremely apt phrase of Hayem, that it is a kind of rigor mortis, or "cadaveric rigidity" of the blood, the writer points out that the act of coagulation furnishes most important data for the study of the physiology of the blood, being a sort of spontaneous analysis the thoroughness of which may be aided by external conditions.

Dr. Andrew Buchanan, of Glasgow, in 1831, after an ingenious investigation, concluded that coagulation was dependent upon the presence of the white blood-corpuscles, the fibrin pre-existing in a state of solution in serous fluids and liquor sanguinis without any spontaneous tendency to coagulate; upon these fluids the white cells acted as a sort of ferment, producing an effect like that of rennet upon milk. Dr. Alexander Schmidt, in 1861, claimed that this action of the white blood-cells was due to their destruction and disintegration, which liberated serum-globulin: this he termed the fibrino-plastic substance. The coagulating property of transudates he found to reside in a substance which he identified also as belonging to the class of globulins, to which he gave the name of fibrinogen. Fibrin he supposed was formed by the combination of these two substances. This view he afterwards modified by invoking the aid of a third agent or factor in the coagulation, which he called the fibrin-ferment.

According to Schmidt's theory, then, blood-coagulation is due to the union of the substances fibrinogen and serum-globulin, under the influence of a ferment,—the first-named being the only one pre-existing in the blood, the others being formed after the blood has been withdrawn from the vessels. Hammarsten has more recently broached the view that the serum-globulin is an unnecessary factor in the formation of fibrin.

In contrast with those who consider fibrin to be caused by the union of soluble substances in the liquor sanguinis, we have the observations of Wooldridge, Norris, Hayem, and Bizzozero,† who attribute its formation, in great part at least, to a transformation of the morphological elements of the blood. The first-named holds the opinion that the plasma changes the leucocytes directly into fibrin, but at the same time a substance is liberated from the cells (fibrin-ferment) which converts fibrinogen also into fibrin. The remaining authorities mentioned agree in associating the formation of fibrin with changes in certain morphological elements of the blood, Norris attributing it to changes in what he terms the invisible corpuscle or advanced lymph-disk, the two others to similar changes in bodies termed by Hayem *hématoblasts*, from their supposed share in the formation of the red blood-corpuscle, and by Bizzozero *blutplättchen*. What the exact *rôle* played by these colorless corpuscles, or blood-plates, may be, is not yet determined, but it has not been established nor even positively claimed that they are the sole agents in the production of fibrin, as the original authorities concede that the white corpuscles also may be concerned in fibrin-formation.

* Vol. xii. No. 3, December, 1884.

† Quoted by Dr. Henry.

In the opinion of Dr. Henry, a blood-clot is the result of two distinct processes,—coagulation proper and fibrin-formation,—the one chemical, the other morphological. Coagulation occurs in milk under the influence of a ferment, but there is no fibrin-formation. "The same process takes place in blood under the influence of a ferment derived from the white corpuscles, and perhaps also from the blood-plates, while at the same time, and in addition, there is formed a fibrinous reticulum which is a direct metamorphosis of the same elements."

It is possible that there may be still a third, and as yet disregarded, factor in the formation of a blood-clot,—*i.e.*, with the chemical and morphological may be conjoined a vital process. The view of the blood which regards it as a living tissue, endowed with physiological energy manifested normally upon condition of its incessant motion in healthy vessels, may also see in fibrin-formation an abnormal and aberrant expression of nutritive force. The term "cadaveric rigidity" of Hayem is certainly very suggestive.

COMMA-BACILLI AND CHOLERA.

THE positive claim of Dr. Koch that the comma-bacillus is the *materies morbi* of epidemic cholera, made in his report to the German government, has not yet been implicitly acknowledged by other competent observers, who have with great care gone over the ground traversed by the great mycologist. Drs. Klein and Heneage Gibbes, in their preliminary report of the result of their investigations carried on in Bombay and Calcutta, declare without any circumlocution that "the statement of Koch that 'comma-bacilli' are present only in the intestines of persons suffering from or dead of cholera is not in accordance with the facts, since 'comma-bacilli' occur also in other diseases of the intestines,—*e.g.*, epidemic diarrhœa, dysentery, and in intestinal catarrh associated with phthisis." Other statements meet with a similar flat denial, and all attempts at inoculating animals with cholera-fluids or bacillus-cultures completely failed. The bacilli in question were cultivated, and it was found by Dr. Klein that they did not behave differently from ordinary putrefactive organisms.

In replying to similar criticisms upon the comma-bacillus recently, Dr. Koch remarked that he remembered that "they made some such remarks about the bacillus tuberculosis two years ago." This is a coincidence which is not without significance.

COLLECTIVE INVESTIGATION.

WITHIN the last week or two there have been distributed to the members of the State Medical Society of Pennsylvania circulars, accompanied by three blank forms, which have been sent out by the Committee on the Collective Investigation of Disease appointed at the last meeting of the State Society. The cards are of different colors, as adopted by the British Association committee, — buff, green, and red,—and are respectively for pneumonia, chorea, and acute rheumatism. The questions have been so arranged as to be answered with the least expenditure of energy and time on the part of the observer, and it is hoped that every member of the Society will feel it incumbent upon him to aid the committee in its work, and will avail himself of the opportunity to report a case of each disease, in order that a fair trial may be made of this method of collective investigation, which is affording such satisfactory results in England. The cards, after being filled up, are to be returned to the address of the chairman, Dr. James Tyson, in Philadelphia, not later than the first day of April, 1885, but the committee requests that they be returned earlier if possible, in order that the labor of their collation may be rendered less arduous.

STATE BOARD OF HEALTH.

A CONFERENCE meeting of delegates from the various local Boards of Health of the State was held at Harrisburg January 13, to take measures looking towards the establishment of a State Board of Health for Pennsylvania. A bill has been carefully prepared, and it is expected that a determined effort will be made to have it passed at the present session of the Legislature. The recommendation contained in the annual message of the Governor has given encouragement to those who have for so long had the matter in charge, and there now seem to be better prospects for such a bill than at any previous session. The Board is to consist of six members, not necessarily physicians, but the Secretary must be a sanitary expert, who shall receive a salary of two thousand dollars a year. The entire appropriation for the Board is limited by the proposed bill to ten thousand dollars.

The members in attendance upon the conference organized a State Sanitary Association, Dr. Green, of Pittsburg, President, which will act provisionally as a voluntary board of health until the bill is passed.

NOTES FROM SPECIAL CORRESPONDENTS.

NEW YORK.

PROFESSOR AUSTIN FLINT ON DYSPEPSIA.

AT the meeting of the New York State Medical Association, November 18, 1884, Dr. Flint read a paper, entitled "Remarks on the Dietetic Treatment of Dyspepsia," in which he gave expression to views which would lead us to suppose that even as great a mind as his may be influenced to lay aside its judicial qualities and take the ground of the extremist. It would seem that, having seen a number of cases of dyspepsia in which the patients were benefited by abandoning their self-regulated diet, the author had allowed himself to conclude erroneously that appetite is an infallible guide in the proper selection of food, both for the well and for the functionally diseased. At the beginning of his paper Dr. Flint makes a, seemingly, very just distinction between indigestion and dyspepsia: "The name (dyspepsia) signifies difficulty of digestion. Now, digestion may be difficult, and attended by more or less suffering and disturbance of the nervous system, the digestive function, nevertheless, being duly and completely performed." But farther on, in speaking of the symptomatology of dyspepsia, he loses sight of this distinction, and applies his remarks to a train of symptoms in which we may justly suppose that indigestion plays a more or less important *rôle;* and for this reason his paper is open to a greater degree of criticism. Indeed, it would be difficult to make a strictly clinical distinction between indigestion and simple dyspepsia (dyspepsia without indigestion). Dr. Flint evidently recognizes this difficulty when, in speaking of dyspepsia, he says that in many instances there is coexisting anæmia, although he adds, "The dyspepsia leads to impoverishment of the blood, often because alimentation is reduced below the needs of nutrition, and this condition tends in no small degree to increase the dyspepsia and render it persistent."

The author's instructions with regard to the diet of persons suffering from dyspepsia seem to us to be particularly objectionable, because, coming from a gentleman of so high authority, they are liable to lead many of his professional brethren and the laity to errors of teaching and living. He says, "Suffice it to say that the maxims which have been enumerated as causative of dyspepsia are to be reversed in pursuing the plan of treatment which it is the purpose of this paper to submit. The instructions, abbreviated, will then be as follows:

"Do not adopt the rule of eating at stated periods,—twice or thrice daily. Be governed in this respect by appetite; eat whenever there is a desire for food. Eat in the evening, or at bedtime, if food is desired. Insomnia is often attributable to hunger. In the choice of articles of diet, be distrustful of past personal experience, and consider it to be a trustworthy rule that those articles will be most likely to be digested without inconvenience which are most acceptable to the palate. As far as practicable, let the articles be made acceptable by good cooking. As a rule, the better articles of food are cooked the greater the comfort during digestion. Never leave the table with an unsatisfied appetite. Be in no haste to suppose that you are separated from the rest of mankind by dietetic idiosyncrasies, and be distrustful of the dogma that another man's meat is a poison to you. Do not undertake to estimate the amount of food which you take. In this respect different persons differ very widely, and there is no fixed standard of quantity which is not to be exceeded. Take animal and vegetable articles of diet in relative proportions as indicated by instinct. In the quantity of drink follow na-

ture's indication,—namely, thirst. Experience shows abundantly that, with a view to comfortable digestion, there need be no restriction in the ingestion of fluids."

We cannot help but feel that in laying down these maxims Professor Flint has reversed those rules which common sense would dictate, and which general experience has proven to be true, and that he has been led to accept the reverse of the truth by having observed certain cases in which persons desiring to follow those rules had failed to do so in fact, and their symptoms had grown worse therefor. At the same time he seems to have overlooked the fact that dyspepsia, in the sense in which he employs the term, may be due to different causes. The affirmative rules to be observed in the treatment of the dyspeptic, the negative of which he recommends, doubtless grew out of the fact that there are different forms or causes of dyspepsia, and it is more than probable that Dr. Flint, in his large experience, has met with examples of these different forms. One person has dyspepsia because his appetite has led him to overeat, in evidence of which we may quote the author of the paper, who says, "The appetite may be more or less impaired, but it is often not diminished, and not infrequently it is increased." Now, if the appetite be increased we may justly suppose that some persons would be ignorant or morally weak enough to cater to their natural inclination and gormandize; and if this be true, the advice to dyspeptics indiscriminately to eat at no stated periods, and to never leave the table with an unsatisfied appetite, could not do otherwise, in many cases, than to work evil. These persons might be able to digest a normal quantity of good food, taken at proper times, without its giving rise to any dyspeptic symptoms or ill health, and their dyspepsia is really due to an excess of food which they are not capable of digesting (therefore due indirectly to indigestion). Were they able to digest all they ate they would fall among those of whom Dr. Flint speaks as follows: "Finally, let us learn a practical lesson from our observations of the class who 'live to eat,'—the *gourmet* and the *gourmand*,—they 'who fare sumptuously every day.' Dyspeptics are not common among this class." But before reaching the age at which they can be classed among those "who fare sumptuously every day" their dyspeptic symptoms become so aggravated that they are obliged to cease "living to eat." The writer once suffered from dyspepsia, which finally led to broken health, brought on when a boy at a time when his appetite was ravenous, and was allowed unregulated freedom, at all hours of the day and night, in the midst of an abundance of tame and wild fruit, vegetables, and a well-supplied pantry. His symptoms of dyspepsia disappeared and health returned only after the rules were obeyed which Professor Flint advises us to disregard.

Again, the statement, "Consider it to be a trustworthy rule that those articles will be most likely to be digested without inconvenience which are most acceptable to the palate," seems to us to be of doubtful propriety. It is just as likely, if one is unable to digest a given kind of food with convenience, that it will be among those articles for which he has an appetite as otherwise. Dyspepsia, in the sense in which it is used by the author of the paper, may reasonably be supposed to be due to a peculiar affection of certain parts of the nervous system, and experience proves that the appetite may demand certain articles of food which, when ingested, affect that part of the nervous system in a manner to produce dyspeptic symptoms.

"Experience shows abundantly that, with a view to comfortable digestion, there need be no restriction in the ingestion of fluids." The author does not say what kind of fluids, but, even if he meant only water and milk, there are, doubtless, many among both physicians and the laity who would reject the statement as too sweeping, and could bring forward abundant evidence showing that persons had injured their powers of digestion by indiscreet drinking of fluids during meals and in the intervals. Several physicians in this city attribute the weak and "run-down" condition, in nearly all cases among their female dispensary patients, to the habit of drinking an excess of tea, or perhaps of coffee. The author seems not to have considered the fact that the appetite for food and drink depends much upon habit, and that many people acquire habits of eating to excess particular articles of diet, of drinking perhaps three or more cups of black coffee with each meal or a large quantity of beer, and of eating at hours when their business will least favor digestion.

Objections might also be made to certain other of his maxims, but we will close by saying it is difficult to avoid the conclusion that Professor Flint, in his desire to correct an apparent tendency on the part of that class of patients of an active mental development to go to a certain extreme, has allowed himself to fall into the error of advising all classes of dyspeptics to go to the opposite and worse extreme. May not this error be due to his practice being largely among the thinking class of people and less among the laboring and uneducated? We should think this probable, inasmuch as he says dyspeptic patients do not belong among hard-working laborers or mechanics. From our observation of men, we have been led to believe that there are many cases of dyspepsia among this class of persons, and here we think the rules which Professor Flint advises all dyspeptics to disregard would be

especially commendable, whereas in the class in which he is most commonly consulted it might perhaps be better advice if they were told to labor more with their muscles in healthful employment, to read and study less, and to follow the promptings of their vegetative system,—appetite, sleep, etc.

One paragraph, including this sentence, "There are various incidental points of inquiry, and certain qualifications of statements, which a full consideration of the subject would embrace," gives the impression that the author does not differ so radically from us in his views of the subject as the general tone of the paper would imply; and, if this be true, we regret that he did not take more time and qualify the statements which may, as they now stand, prove to some a stumbling-block in the way of recovery from dyspeptic, and also general digestive, disorders.

PROFESSIONAL NOTES.

The Medical Department of the University of the City of New York has sustained a serious loss in the death of William Darling, M.D., LL.D., F.R.C.S., for many years Professor of Anatomy. Dr. Darling was said to be given to eccentricities, and among others was one which students of medicine would be glad to recognize in all teachers,—viz., that of beginning and ending his lecture on the stroke of the clock. It has been reported that none of Professor Darling's relatives survive him; but a physician-friend told me that he is acquainted with one of his brothers, who resides at or near Burlington, Iowa.

It has been over two weeks now since Dr. Richard C. Brandeis disappeared, and up to the time of this writing no information has been received of his whereabouts. Dr. Brandeis was a graduate of the College of Physicians and Surgeons (1871), and was one of the Professors of Diseases of the Nose, Throat, and Ear at the New York Polyclinic.

About a week ago Dr. Rudolph Tauszky shot his wife and then himself, the ball in both cases striking the head, but probably not inflicting wounds which will cause death. It is thought that he was temporarily insane when he committed the deed. Dr. Tauszky has been a liberal contributor to medical literature, had made more or less a specialty of the diseases of women, and had recently testified as a medical expert in several cases of insanity.

A number of cases of typhus fever have developed in a West Thirty-second Street tenement-house, and the health authorities are having a little trouble in stamping out the endemic. One hundred and fifty-seven cases of measles were reported by the Board of Health for the week ending January 6, fifty-nine of diphtheria, fifty-eight of scarlet fever, and thirteen of typhoid fever.

The Directors of the New York Dispensary hereafter propose to appoint three physicians who shall have passed a competitive examination, paying them a salary of eight hundred dollars annually for services of three or four hours' duration at the daily dispensary. Would not this be a good plan for diminishing the unnecessarily large number of our free dispensaries and so-called hospitals? But so long as the city physician remains as ambitious as he at present appears to be to have his name connected with some public institution, this change for the better will probably not be brought about except through the co-operation and instrumentality of directors of hospitals and dispensaries. The question might suggest itself to the curious whether in any given case the change was not due to a supposition that better services would be rendered the sick poor by a few physicians who received the moral support of a pecuniary consideration than by a larger number, who, inasmuch as their services were entirely uncompensated, might feel themselves justified in trying to advance their medical skill and reputation by practices which would be rejected by one whose eye was single to the good of his patients. R. C. S.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a clinico-pathological meeting of the Society, held at the Hall of the College of Physicians, December 17, 1884, the President, Dr. W. M. Welch, in the chair, papers were read by Drs. J. M. Barton (see page 316), Dr. W. C. Hollopeter (see page 304), and others.

DISCUSSION ON INVERSE TEMPERATURE IN TYPHOID FEVER.*

Dr. J. C. Wilson, in opening the discussion, said, "The paper of Dr. Hollopeter is very interesting and suggestive. It touches upon or suggests almost every important clinical problem relating to this disease. Its free discussion, therefore, would be impossible in one, or indeed in many evenings. Two or three points call for special consideration.

"First, the typical temperature-curve and its variations. The well-known course laid down by Wunderlich as a standard is met with perhaps less frequently than strongly-marked variations. Nevertheless, a knowledge of that course is the key to the understanding of the variations from it. Wunderlich, after describing the course of the first four or five days, lays down the law that every case which does not conform to this temperature-type is not typhoid fever. This dictum has been the source of manifold er-

* Reported by G Betton Massey, M.D.

rors in diagnosis. No more fallacious statement could be made. Cases of undoubted typhoid fever constantly occur in which the range of temperature fails to conform to the typical curve, not only in the beginning of the attack, but throughout the whole course of the disease. In fact, cases sometimes occur, the nature of which is fully established by the complexus of symptoms and the existence of local epidemics, in which the temperature remains throughout even *sub-febrile*. The singularly labile temperature in this disease, rising and falling, as it does, under very slight disturbing external influences, makes it a matter of surprise not that the temperature is not always typical, but rather that it ever closely conforms to the type.

"Second, the inversion of the diurnal range, of which Dr. Hollopeter has given two instances, is not common. I have seen cases of it, to which I will briefly refer. I am not aware that any adequate theory of this curious clinical phenomenon has yet been advanced.

"Third, house-epidemics. The second part of the paper, which considers the details of this curiously circumscribed and localized outbreak, is very interesting and important. It is by the study of such house-epidemics that a true insight into the etiology of the disease is to be gained. I do not agree with the author of the paper in ascribing the disease in the infected house to the percolation of waste-water through the cellar-wall from the adjoining premises. In order to establish this theory it would be necessary to show, first, that such percolation, if capable of producing this disease, had not been going on for an indefinite time prior to the attack, and, secondly, that typhoid fever had existed in the neighbor's house, or at least that the dejecta of typhoid patients had been thrown into the pit from which the drainage into the cellar ran. These facts have not been shown. On the other hand, it appeared clear enough that the first case, the young woman who had come home sick from another house, had introduced the disease. An investigation of the house and neighborhood from which she came would doubtless shed light upon the subject. House-epidemics are numerous in Philadelphia. Certain houses, however, seem to be the abiding place of the infecting principle, seeing that cases occur in them from time to time during a series of years."

Dr. E. T. Bruen: "I have been very much interested in Dr. Hollopeter's paper, and also in the remarks of Dr. Wilson. I agree particularly with the portions relating to the contagion. Two cases recently seen by me illustrate this. A washerwoman took home the clothes of a typhoid-fever patient. Within a week her two children drooped and became feverish. They were taken to the Children's Hospital, and one died there with no autopsy. The other was taken home, where it died, and I made a post-mortem examination. The typical conditions were present. No other cause for their sickness was known.

"I am also interested in what Dr. Wilson has said about alterations of temperature from slight causes. We notice the same thing in diseases of the liver, in which cases the thermal wave fluctuates with the ingestion of food. If we admit these causes, I think we can readily admit psychic influences in the same *rôle*.

"In diagnosticating typhoid fever, it is to be distinguished from malarial fever and catarrhal fever. Malarial fever is *sui generis*, and can be controlled in this latitude by quinine. I believe that malaria will modify the initial stages of typhoid fever. Thus one of the groups of cases called typho-malarial takes its name. Neglected malarial fevers form another group of so-called typho-malarial fever, which is not a disease *sui generis*.

"I have seen many cases of mild typhoid fever,—the so-called typhoid ambulatorius. Throughout these cases have shown a temperature of 100°, not over 100°, but I would not make the diagnosis of typhoid fever if the temperature after the fifth day fell below 100° in the evening.

"Catarrhal fever is characterized by peculiar weakness, with various catarrhal conditions of lungs and bowels. The temperature runs from 99° to 100°, and is at times almost normal. Such cases should be classed as catarrhal fever, and are very similar to the specific forms of influenza. They may be recognized by the fact that the temperature is very irregular, and it is impossible to control this feature by quinine. I think these are the cases which have often been confused with mild typhoid."

Dr. Baldwin: "Dr. Levick some time ago published a paper in which he spoke of a family predisposition to typhoid fever as well marked in some families as that of phthisis. I should like to ask Dr. Wilson if he has noticed any cases of like character."

Dr. B. Trautmann: "Niemeyer speaks of inverse temperature in typhoid fever, and says that these cases end generally fatally. This seems to disagree with the statements made here to-night. I have at this time a case showing this curve, in which a hemorrhage of the bowels followed this morning."

Dr. Kevin: "I have also a case now under treatment showing inverse temperature."

Dr. Arthur V. Meigs: "With regard to the etiology, I do not think Dr. Wilson's position is well taken. In the face of the authority of Murchison that typhoid fever may arise *de novo*, it seems to me hardly fair to assume the germ-theory as proved, although the medical mind seems at present to be inclined in that direction. Typho-malarial fever has always seemed to me a bad name, for it misleads; it means in its proper sense a hybrid,—both malarial disease and typhoid

fever co-existing in the body at the same time."

Dr. W. A. Edwards: "In the case of a young man under my care whose temperature presented the peculiarities spoken of, a diagnosis of double quotidian was made. On the eighth day signs of typhoid fever set in, and lasted four weeks, then again there was a typical double quotidian. If the case had not been so diagnosticated, it would have been put down as a case of typhoid fever with inverted temperature. This, with other cases, I published in the *Medical and Surgical Reporter*, November 17 and 24, 1883, and mention it to-night to call attention to the fact that all cases of inverted temperature in typhoid fever are not due to the typhoid entirely, but frequently to a complication, this complication occasionally being almost unrecognizable except for its effect on the temperature."

Dr. Wilson: "A clear comprehension of the mode in which typhoid fever is propagated from previous cases by means of a specific infecting principle is of the utmost importance. Murchison, it is true, held that it might arise *de novo*. Nothing in the literature of the subject is more brilliant than that great author's advocacy of this view, and the student of the subject knows that it was maintained in Murchison's day with a vigor scarcely inferior to that with which it has been defended here, with more success. To Dr. Wilson Budd, of Bristol, is due the credit of showing that Murchison's view was untenable. To-day it is no longer entertained."

Dr. Meigs: "I did not pretend to deny that a single case of typhoid fever may be the focus from which any number of others may arise. I merely contended that, in the face of Murchison's opinion that the disease may arise *de novo*, we should be careful how we assume as proved the germ-theory."

Dr. J. Solis Cohen: "I do not rise to speak directly to the subject of the paper, as I do not see typhoid fever except in hospital practice. Many years' observation has convinced me that sudden rises of temperature in typhoid fever, as in other diseases, are often due to obstruction of the bowels, even though diarrhœa may exist. A small dose of castor oil will usually quickly relieve the bowels and reduce the temperature. The ordinary milk-diet is then to be modified by the addition of lime-water, or by substituting boiled milk for cold. My residents have for years had general instructions to pursue this plan without awaiting my daily visits.

"The family epidemic recorded reminds me of a similar one in a German family, the members of which were distributed to several hospitals, three of them coming under my own care. A marked local epidemic occurred among the sailors on board the Russian war-vessels which several years ago were lying off the wharf at Kensington, some sixty of whom came under my care with the most typical demonstration of the true typhoid curves that I have ever seen. The temperature-charts looked as though they might have been copied from a text-book. The cause in these instances was the drinking of water from the Delaware River, which the sailors, following an old custom, dipped from the side of the vessel to within a few feet of the open outlets of sewers.

"I was very much interested in the story of the poor washerwoman's family. Our duty in the presence of contagious disease is very clear, and is too much neglected by physicians. We should not allow our patients to send clothes out to be washed until they have been thoroughly disinfected. Indeed, rather than subject a family to contagion, let the clothes be burned. Many a poor washerwoman in this city brings typhoid fever, diphtheria, and other diseases to her household through the carelessness or indifference of her customers."

Dr. Hollopeter, in closing the discussion, said, "I had felt a certain uneasiness in presenting my cases of *inverse temperature*, as I could obtain but little authority for the same; yet I have recorded the simple facts, and am glad to learn that other members have also noticed similar cases. In a future paper I hope to give more of the literature of the subject. In answer to Dr. Wilson as to the causation of the house-epidemic, I would state that Mary, the first to take sick, was at the time not living at home, yet she frequently came home for a few days at a time. The family she was working in were all healthy."

PHILADELPHIA NEUROLOGICAL SOCIETY.

THE regular stated meeting was held December 22, 1884, the Vice-President, Dr. CHAS. K. MILLS, in the chair.

Dr. MILLS read a paper on the treatment of epilepsy, of which the following is an abstract:

NOTES ON THE TREATMENT OF EPILEPSY.

His remarks applied chiefly to the medicinal treatment of epilepsy proper,—grand mal and petit mal. He did not intend to refer to the treatment of convulsive seizures due to tumors, meningitis, spinal disease, etc.

As to the curability of epilepsy, some apparently authentic cases of cure were on record. After looking over the subject, he could only recall seven cases of apparent or real cure in his own practice, private and hospital. In all of these the attacks remained away for from more than one to more than three years. Gowers mentions a number of cures,—at least, cases in which seizures had not recurred for as much as four, five, six, or seven years. Several of these cases were children. Three

of the seven cases alluded to by Dr. Mills were children. All observations as to the cure of epilepsy were necessarily imperfect. After a number of years the attacks recur again. Although, however, the absolute curability of epilepsy might be doubtful, certainly great benefit from treatment is to be derived in most cases. It is a wrong to such patients not to treat them.

He had used the following remedies, singly, three or four times daily, in a series of cases, during the last ten years: Bromide of potassium, grs. x to ʒj; bromide of sodium, grs. x to ʒj; bromide of ammonium, grs. x to ʒss; monobromide of camphor, grs. iij to vj; hydrobromic acid, fʒss to fʒss; iodide of potassium, grs. v to ʒss; biborate of sodium, grs. xv to xx; chloral hydrate, grs. x to xv; oxide of zinc and valerianate of zinc, grs. iij to x; nitrate of silver, gr. ¼ to gr. ½; tincture of belladonna, ♏x to xv, or extract of belladonna, gr. ¼ to gr. ½; extract of cannabis indica, gr. ⅛ to gr. ¼; fluid extract of cocculus indicus, ♏j to iij, or tincture of cocculus indicus, ♏v to x; nitrate of potassium, grs. v to viij. Other remedies, which he had only used in combination with some of the above drugs, were as follows: Conium juice, fʒj, or fluid extract, ♏iij to x; tincture of digitalis, ♏v to x; sulphate of strychnia, gr. $\frac{1}{40}$ to $\frac{1}{30}$; Fowler's solution of arsenic, ♏ij to v; fluid extract of ergot, fʒj to fʒij, or extract of ergot (Squibb's), grs. iij to vj; iron, cod-liver oil, and quinine.

The bromides were certainly the best remedies, and the bromide of potassium, in his opinion, stood at the head of the list. The bromide of sodium came next best to the bromide of potassium. He thought the bromides affected the nerve-centres directly. The mixed bromides were better, usually, than any one of them used singly.

The bromides could be advantageously combined with other drugs. The combination which he had found, on the whole, the best for long-continued use was bromide of potassium, grs. xv; bromide of sodium, grs. xv; solution of the arsenite of potassium (Fowler's solution), ♏ij; conium juice, fʒss, or the fluid extract of conium, ♏iij to v. This was generally made up with syrup of orange and some bitter infusion.

Another good combination, mentioned also by Gowers, was the bromide of potassium and tincture of digitalis. It was only especially valuable in cases complicated with weak heart or mitral disease. Monobromide of camphor had no advantage over the bromides. Hydrobromic acid was efficient in very large doses, but so much water had to be given with it that the amount to be swallowed was appalling to the patient. It sometimes irritated the stomach. Borax was not of established value, but helped a few cases temporarily. He found the iodide of potassium, unless especially indicated, had little value when used alone in the treatment of epilepsy. Chloral hydrate is not of much value when given alone, but with the bromides, in cases uncomplicated with cardiac disease, it sometimes makes a useful combination. Trousseau's belladonna treatment had been used without noteworthy success. Cannabis indica was not to be depended upon. He had tried cocculus indicus in six cases at the Philadelphia Hospital. None improved, and four were made worse by its use, one of the four becoming insane while taking the drug. At the request of Drs. Reichert and Hinsdale, he had used the nitrite of potassium in seven cases. Of these, only one seemed to be benefited, and some were made worse by its use. When the bromides had to be stopped, the zinc salts or the nitrate of silver were the best substitutes, but they could only be relied on for a short time.

The way to treat epilepsy, in his opinion, was to simply have a plan of treatment, and carry it out over a series of months or years. He would, for instance, first put a patient upon a single bromide, say fifteen grains three times a day, to be increased until a decrease in the number and severity of the paroxysms was produced. He kept him upon this perhaps for a month. He then used the mixed bromides, or some combination of bromides with other drugs, preferably the bromides, arsenic and conium prescription. He watched the condition of the patient, and, if necessary, also put him on cod-liver oil, quinine, or iron.

With reference to nitrates, bromates, etc., he said that there was probably some chemical or chemico-physiological reason for inefficiency. The *ites* and *ates* would probably never give as good result as the *ides*. Dr. Mills believed with Dr. Pepper (*Med. and Surg. Reporter*, January 12, 1884) that close attention should be paid to every point in the daily life of an epileptic,—to diet, rest, and hygiene; but he did not, with his present experience, believe that a genuine case of thoroughly-developed epilepsy could be cured, or even greatly benefited, without drugs. Harm, however, might be done by over-use of drugs.

Among the surgical and external means of treatment he had successfully used were excision of cicatrix, removal of neuroma, actual cautery, and blistering to the neck or head. He said he did not use counter-irritation to the scalp, but was a strong believer in the actual cautery, used after Brown-Séquard's method, to the nape of the neck.

DISCUSSION.

The discussion was opened by Dr. E. T. REICHERT. He said that the efficacy of the bromides was certainly not due to the bromine, for bromide of potassium is the best of the bromides, and it contains less bromine than any of the others. The amount of

bromine in the chief bromides, as given by Gowers, is as follows:

Bromide of ammonium	.	81 per cent.
Bromide of potassium	.	67 "
Bromide of sodium	.	77 "
Bromide of lithium	.	92 "

All the bromides act alike, but with varying degrees of efficiency. The bromates, nitrites, etc., are not as useful as the bromides. A certain line of similar chemical salts seem to give uniform physiological and therapeutical results.

Dr. Guy Hinsdale said that, in regard to the cases in which Dr. Mills used the nitrite of potassium, some four years ago, one was benefited, some remained the same, while others were apparently made worse by its use.

Dr. Wharton Sinkler wished to know if any of the members of the Society had used hyoscyamus, and with what results. He said that Althaus, of London, reported cases in which tincture of hyoscyamus had been used successfully in doses of from one, two, or three drachms. He said that he had reported one case of epilepsy which had been greatly benefited by cannabis indica, after the bromides and other remedies had failed.

Dr. H. M. Wetherill said that, in his experience, the bromide of potassium was the best remedy. He said he had never tried the tincture of hyoscyamus. He had never seen a case of epilepsy entirely recover.

Dr. F. Dercum said that his experience was summed up in the statement that he had found the bromides the best.

Dr. Morris Lewis spoke of the cure of a child 3 years old, at the Episcopal Hospital, in which he could obtain no results with the bromide of potassium. The seizures continued, and were worse, if anything. He then resorted to bromide of ammonium, and with immediate good results.

Dr. J. H. Lloyd said he thought that in cases of epilepsy attention to the digestive functions and to sleep was highly important. He called attention to the observation of Dr. Radcliffe, that epileptics have a tendency to overeat and to sleep too much. In his own experience he had found that when constipation was present the seizures were likely to be more frequent and severe. Dr. Radcliffe and other English physiologists seemed to prefer comparatively small doses of the bromides long continued. Dr. Lloyd believed the combination of three bromides with the iodide of potassium to be one of the best in the treatment of epilepsy.

Dr. A. J. Parker said he believed we could not say that the effect of a drug like bromide of potassium, bromide of sodium, etc., was due either to the bromine, or potassium, or the sodium, etc. Each of these salts is an individual drug, each molecule of which has its own form of motion. Bromine is a substance with its own peculiar molecular condition of motion. Potassium, similarly, has its own motion. Bromide of potassium is the resultant of the two motions. Certain members of the same chemical families, as the bromides, iodides, and chlorides, would seem to go together in therapeutical efficacy, due to similarity of their forms of molecular motion. At any time we may expect, however, to find wide differences, since our chemical equations simply represent an idea of structure, and tell us nothing concerning the form of molecular movement; and therapeutic effects must certainly depend more on the energy and form of motion than upon any other qualities.

Dr. E. T. Reichert made a few remarks on the use of

HYDROBROMIC ACID AND THE BROMIDES IN SEA-SICKNESS.

He said, while crossing the ocean, he had the opportunity of studying the effect of hydrobromic acid and some of the bromides in sea-sickness. Hydrobromic acid was effectual, but had to be used in such large doses that, owing to the dilution with water necessary, the bulk to be taken was excessive. The bromides were therefore, he thought, to be preferred. Bromide of sodium, in large doses, was effectual in one bad case. He believed that all the bromides were good.

Dr. J. M. Taylor spoke of the use of

NITRITE OF POTASSIUM IN ANGINA PECTORIS.

In an aggravated case of angina pectoris he had obtained very good results with nitrite of potassium. The patient had been suffering for over a year with paroxysms of increasing intensity, until death seemed imminent. After giving the nitrite of potassium for four weeks the patient recovered. Nitrite of amyl was used sparingly, to control the paroxysms.

Lewis Brinton, M.D.,
Recorder.

PHILADELPHIA CLINICAL SOCIETY.

At a stated meeting held November 28, 1884, Dr. Henry Beates in the chair, Dr. Roberts read a paper entitled

NOTES ON SOME INSTRUCTIVE CASES OF HERNIA.

He reported cases illustrating reduction of an irreducible femoral hernia of seven years' standing, irreducible incomplete hernia, recovery from strangulated hernia without operation, herniotomy for strangulated femoral hernia in a paralytic, and others. He desired to emphasize particularly the following points:

That inguinal and femoral hernia will be found at the same time on the same side much oftener than is supposed.

That it is safer to operate in cases of sus-

pected strangulation than to postpone operation beyond twelve hours.

That herniotomy is attended with little hemorrhage, and, if done antiseptically, is accompanied by rapid union and little risk to life.

DISCUSSION ON DR. ROBERTS'S PAPER.

Prof. JAS. B. WALKER: In connection with Dr. Roberts's paper, a brief narration of the salient points of the following cases may be of interest:

Case I.—A lady, aged 79, as the result of a fall noticed a swelling in the left groin below Poupart's ligament, in the vicinity of the femoral ring. The tumor soon occasioned marked disturbance. It was of doughy consistency, and cough failed to impart succussion. Percussion did not elicit a tympanitic note, and taxis failed to reduce it. As there was a doubt of its real nature, anæsthesia was induced with ether, and still taxis failed. The existence of symptoms of strangulation —viz., constipation, nausea, and vomiting— determined operative procedure, when an entero-epiplocele was disclosed. The omental element was the greater, and enclosed a small knuckle of gangrenous intestine; this constituent of the tumor was so small that the ordinary symptoms of succussion and tympany were rendered non-detectable. Hot water failed to develop manifestations of vitality, so the section of intestine was excised and the healthy ends stitched together. Suppression of urine followed the operation, and death resulted on the third day.

Case II. was an instance of inguinal hernia in a female advanced in years. Efforts at reduction by a number of physicians had failed. Notwithstanding the length of time intervening, by properly applying taxis, he succeeded in reducing the tumor. The probable cause of failure on the part of other attendants was improper attempts at taxis. The mass pressed out over the ring in a manner to defeat their object. This is, in a majority of instances, the undoubted cause of failure of efforts at reduction.

Case III.—A male with complete right inguinal hernia, strangulated. Taxis failing, an operation was resorted to, but the case terminated fatally. The peculiarity consisted in a deposit of fibrin or lymph nearly two inches in thickness surrounding the external ring.

Case IV.—A gentleman, whose vocation required at times heavy lifting, complained of a peculiar burning or stinging pain limited to the right inguinal region. There was no perceptible tumor. The symptoms were invariably aggravated by physical effort. I diagnosticated incipient inguinal hernia, and advised a truss. The patient, being dissatisfied, consulted an irregular physician, who ridiculed the diagnosis given, and administered homœopathic powders for nearly four weeks, with, of course, no result. By this time the hernia was protruded and unmistakable. The patient now wears a proper truss, and is practically well.

In reference to umbilical hernia, I wish to call attention to the fact that the umbilical opening is comparable to the cranial fontanels in that, like the latter, it gradually closes with advancing age. Basing my plan of treatment on this physiological fact, I support the abdominal walls with a broad adhesive strip so applied as to approximate the umbilical region. To the umbilicus I adjust a compress smaller than the opening. This prevents protrusion without interfering with the closing process.

Dr. J. G. HEILMAN narrated the history of an aged colored man who suffered from an inguinal hernia, which became strangulated. Anæsthesia with chloroform did not render reduction practicable. Drs. E. R. Stone and L. B. Hall were called in, and, at the suggestion of the former, about a fluidounce of a straw-colored fluid was evacuated from the sac by means of an ordinary hypodermatic needle. After this procedure the hernia was easily reduced, and a favorable result followed.

Dr. L. BREWER HALL directed attention to the high prices asked by instrument-makers for trusses, and inquired if there was any way by which the poor could get them at more reasonable rates.

Dr. WALKER, in reply to Dr. Hall, explained how a ten-dollar truss could be obtained from a Chestnut Street dealer, under such circumstances, for seven dollars.

Dr. ROBERTS, in closing the discussion, said, "In my opinion, the mortality in cases of hernia is due to two causes,—first, too great an effort at taxis, whereby inflammatory changes are occasioned and surgical treatment complicated and endangered; second, delay. If gentle taxis fails, herniotomy should promptly be performed. The conditions of delay and experimental manipulation by students in hospitals render hospital statistics of little value. In one case of double hernia (*i.e.*, an inguinal and femoral hernia on the same side) I succeeded in maintaining them in place by an inguinal truss so depressed as to occlude both the external abdominal ring and the femoral ring. In umbilical hernia I apply a compress moulded of wax instead of the coin. It is more readily adapted to the size of the orifice and kept in close apposition."

Dr. STONE'S paper was then read (see page 309).

DISCUSSION ON THE MANAGEMENT OF LABOR.

Prof. J. B. WALKER agreed so fully with the points advanced by Dr. Stone that discussion seemed almost superfluous. He believes that the method described of hooking the placenta from the uterus with the finger is

one in which there is considerable danger of introducing disease-germs, because of carelessness and want of cleanliness on the part of accoucheurs. Therefore, for a general rule, it should be taught that expression should be persevered with until the placenta is forced into the vagina. Hot injections of pure water he believes to be especially useful, and the dangers following this practice, so emphatically declared by hospital experience, are a myth, and should not deter private practitioners from their employment. In hospitals, where one syringe serves for many cases, there is danger, but in private practice, where new instruments can be had and their use limited to the individual, danger does not obtain; on the contrary, the risk of infection by a nurse whose clothing may have been subjected in previous cases to septic poison is by this plan of treatment greatly diminished. Again, these injections of hot water overcome inertia. They exert a powerful oxytocic influence and promote favorable physiological processes. If these injections during the lying-in period fail to cause firm uterine contraction, quinia should be administered.* The use of ergot in the third stage of labor is a moot question possessing so much of *pro* and *con* that I do not feel in a position to state invariable rules regarding its employment.

Dr. E. MONTGOMERY thoroughly indorsed Dr. Stone's paper. He calls especial attention to the great importance of resorting to diagnosis of the presentation and position by external palpation performed during the last month of gestation. He has recognized faulty conditions and been able to correct them, thus securing the advantages of a normal labor to both mother and child. He makes it a rule to visit his patients during their last month, diagnosticate the position, and at the same time ascertain the general condition. The unusually small number of lacerations of the perineum is a conspicuous feature in the doctor's experience, and argues strongly the skill attained and the commendable care with which he conducts his cases. The position described in which the obstetrician should place himself in order to command better control of the patient during the period at which the head and shoulders are being extruded is one of great advantage, and one which enables the attendant to avert this lesion in many instances. Cervical lacerations are of very frequent occurrence. Many spontaneously heal to such a degree as to be practically cured. Traction on cord combined with fundal compression is my method of delivering the placenta. A twisting movement is always a valued resort, it converts the membranes into a rope like mass, which reduces the possibility of tearing and leaving portions within the uterus to a minimum, and maintains firm uterine contraction, which is always followed by excellent results. Ergot should not be administered as a routine method, as many conditions may be present the treatment of which the effects of this drug would compromise: adherent placenta is an instance. Regarding anæsthesia, the prompt and transitory effects of ethyl bromide, and its freedom from danger when used as obstetric conditions demand, render it an especially valuable drug. It does not interfere with uterine contractions, is not followed by inertia or unpleasant effects. Several instances of sepsis have occurred in my private practice that cannot be traced to hospitalism or to attendance upon diseases that supply the septic poison, as scarlatina, erysipelas, etc. As a consequence, he always employs corrosive mercuric chloride, cleansing his hands with it before making the necessary examinations and manipulations. After accouchement, he directs the vulva to be covered with a pad saturated with a solution of the chloride. This is changed about thrice in twenty-four hours. Since resorting to this he had not had one case of septic disease occur in private practice, and in that hot-bed of septic poison, the Philadelphia Hospital, where every year he formerly had many cases of puerperal fever, but two cases occurred. The practice of injecting the vagina in a hospital is apt to serve as a means of introducing sepsis.

Dr. ROBERTS called attention to pellets of corrosive sublimate, prepared by a pharmacist, that serve as a convenient form for carrying and having for use this remedy. He has not had experience with ethyl bromide in light anæsthesia, and cannot say whether or not, used in this way, it is a safe drug. In the profound anæsthesia required in surgery his experience compels him to regard the drug as not free from danger.

Dr. STONE, in closing the remarks, detailed the conditions of laceration and the results of non-surgical but careful treatment, which, as the results were practically those of cure, rendered the percentage-report apparently unusually favorable.

* I have never in private practice seen a single case of septic disease induced by injections. Hot water alone is all that is necessary. In one instance, where the phenomena of sepsis were developing and decidedly established, the symptoms were promptly relieved by hot water alone. J. B. W.

CHICAGO GYNÆCOLOGICAL SOCIETY.

REGULAR MEETING, DECEMBER 19, 1884.

The President, H. P. MERRIMAN, M.D., in the chair.

DR. W. H. BYFORD read a paper entitled

A CASE OF MURAL PREGNANCY.

The history of the case was obscure. The patient, 28 years old, married seven years, had one child, six years old. She supposed

that she became pregnant for the second time in February, 1883. In April, after being fatigued, she had hemorrhages, which continued until May 9, about four weeks. October 14 a discharge of yellow fluid, about one gallon in quantity, occurred. A putrescent, sero-sanguineous discharge followed, continuing three months. January, 1884, a large brownish mass with very fetid odor was expelled. After this event menstruation occurred until July. In May she was quite large and had bearing-down pains. She entered the hospital October 6, 1884. She was tapped October 18, and about four quarts of thick, tenacious fluid, resembling the fluid of an ovarian cyst, were removed. This fluid coagulated on the addition of nitric acid and on boiling. Assisted by Dr. R. Filley, a microscopical examination was made, with negative results. The "Drysdale" cell was not found. Laparotomy was performed, and a fœtus with placenta was removed without hemorrhage or difficulty. In order to secure perfect drainage it was considered best to remove the uterus. The operation was performed on October 30. The patient did not react, but died within twenty-four hours. Prior to the operation the patient was extremely reduced by her protracted sufferings. Dr. Byford in a similar case at the present time would elect the vaginal operation. The specimens removed from this woman were exhibited as supporting the diagnosis of mural pregnancy.

This was the second case of mural pregnancy that had come under the reader's observation within a period of five years. The first case was reported to this Society some time ago. The patient was in labor and moribund when Dr. Byford saw her. She had been in labor until exhausted. There was no difficulty in making a diagnosis. The head was low down in the pelvis, almost on the perineum. The os uteri was wellnigh inaccessible behind and above the symphysis. The body of the uterus, somewhat enlarged, could be felt in the lower and anterior part of the abdomen, attached to the tumor containing the fœtus. The fœtus could be felt through the abdominal walls, surrounded by a thick involucrum apparently as thick as the uterine walls. Fœtal extremities could be distinguished. When dissected, the sac in which the fœtus was contained was found to consist of a thick layer of muscular fibres. These fibres were directly continuous with those of the uterus. The tubes and ovaries lay upon the sides of the lower portion of the sac. The fecundated ovum had made its way down the tube, became lodged in a diverticulum in the uterine wall, and was gradually extruded into the cavity of the abdomen. The fœtus was thus developed within the uterus, though not within the uterine cavity. The resemblance to normal pregnancy was great in the presentation and position of the fœtus, deep down in the pelvic cavity, behind the vagina. The head in this case was fixed by the concentric contraction of the uterine fibres by which it was surrounded, and could be easily outlined as it lay thus covered by the posterior vaginal wall.

The specimen presented is much less perfect than the one described, because of the numerous effects wrought upon it during the great length of time it remained in the maternal body and the mutilation consequent upon enucleation.

The treatment of these cases ought to be considered apart from that of extra-uterine pregnancy at term. It is always a matter of special consideration, in connection with each case as it presents itself, whether or not the removal of the fœtus at term in extra-uterine gestation should be attempted. The dangers of laparotomy are greatly increased by the inability to remove the placenta. The surface to which it is attached has no contractile power, so that the divided vessels are left patulous. If hemorrhage does not immediately prove fatal, the blood is a source of sepsis that must almost certainly destroy the patient. Laparotomy would more likely prove successful if performed some days after the death of the child. In these cases of ectopic or interstitial uterine pregnancy the fœtus may be easily removed through the vagina. An incision made through the posterior vaginal wall would completely uncover the presenting part and enable one to apply the forceps or attack it with the perforator and crotchet as in ordinary labor. After the removal of the fœtus the placenta should be allowed to separate spontaneously.

Since writing this report, Dr. Byford had seen a case reported in the *Annales de Gynécologie*, July, 1884, occurring in the practice of Mr. Matheson, of England, illustrative of the execution of this plan. The case was reported to the London Obstetrical Society under the title "Extra-Uterine Pregnancy: the Extraction of a Living Fœtus through the Vagina." The child was slightly asphyxiated, but survived. A sponge saturated with perchloride of iron was introduced into the sac after removal of the placenta. The mother recovered. It would seem that the author did not suspect his case to be one of interstitial pregnancy. During the discussion that followed, only one of those present expressed the opinion that it was of that variety. Mr. Griffith thought it was either interstitial pregnancy or one in which the fœtus was developed in one portion of a double uterus.

A general discussion followed the reading of the paper, in which Drs. Edward Warren Sawyer, E. C. Dudley, J. H. Etheridge, A. Reeves Jackson, John Bartlett, W. W. Jaggard, Charles W. Earle, and Dr. Byford participated. Some difference of opinion being expressed, the specimen was referred for ex-

amination to a pathologist, not a member of the Society, for report at the next regular meeting.

Dr. Etheridge presented a specimen of a placenta containing calcareous deposit from a woman whose pregnancy had extended to two hundred and ninety-two days.

W. W. JAGGARD, M.D.,
Secretary.

REVIEWS AND BOOK NOTICES.

CONVERSATIONS BETWEEN DRS. WARREN AND PUTNAM ON THE SUBJECT OF MEDICAL ETHICS: WITH AN ACCOUNT OF THE MEDICAL EMPIRICISMS OF EUROPE AND AMERICA. By FRANK HASTINGS HAMILTON, M.D. Bermingham & Co., New York, 1884.

The vexed question of the utility of the National Code of Ethics has been so diligently urged in New York State as, in effect, to divide the profession of the Empire State into two partisan camps, with a state of feeling existing between the two which is truly deplorable and highly discreditable. It has led to the establishment of rival county medical societies and a rival State medical society, by which the breach between the two parties will be perpetuated. One of the peculiarities of the new-code, or no-code, advocates is their refusal to discuss medical ethics from any higher point of view than a purely business standard, and consequently they are impervious to most of the arguments of their opponents. Were this not the case, we think that this admirable publication of Dr. Hamilton and the writings of Drs. Flint and Squibb would be sufficient to re-establish the authority of the Code. The series of interesting supposed conversations of Drs. Putnam and Warren completely cover the ground upon which the Code is founded, and fully maintain its teachings and answer the objections which have been raised by its critics; but, in conclusion, the author suggests that certain amendments might be made which, without altering its spirit, would increase its efficiency and acceptability.

YEAR-BOOKS OF MEDICAL PROGRESS.—A YEAR-BOOK OF THERAPEUTICS FOR 1883, Edited by ROYAL W. AMIDON; and A YEAR-BOOK OF SURGERY FOR 1883, Edited by CHARLES H. KNIGHT, M.D. G. P. Putnam's Sons, New York, 1884. Cloth, 8vo.

These handsomely-printed volumes furnish a well-selected and classified digest of medical and surgical contributions to the literature of the science in the year 1883. The matter is conveniently arranged for reference, and, being well edited, the works are both convenient and useful. To those who are engaged in the almost vain effort to keep up with current medical literature these year-books furnish comfort and satisfaction, as they represent an annual taking of stock, and a sifting of the wheat from the chaff. The surgical volume has no index, but its table of contents and careful arrangement under sub-headings may render an index unnecessary. An index of authors would facilitate reference, and might sometimes prove very useful. Bibliography has not been attempted to any great extent, as that is furnished by the "Index Medicus," to which these volumes are useful supplements.

THE ELEMENTS OF PATHOLOGY. By EDWARD RINDFLEISCH, M.D. Translated from the First German Edition by W. H. MERCUR, M.D.; Revised by JAMES TYSON, M.D. Philadelphia, P. Blakiston, Son & Co., 1884. 12mo, pp. 263.

The subject-matter of this work is an outline sketch or groundwork of pathology, without having any pretensions as a text-book. Having this in mind, the various sections of the (*a*) general part, on (1) the Local Outbreak of Disease, (2) the Anatomical Extension of Disease, (3) the Physiological Extension of Disease, followed by (*b*) Animal Disturbances, and the special part, including Traumatic, Parasitic, and Infectious Diseases, Defective Development and Growth, Diseases due to Overwork, and Diseases of Involution, may be read with interest and profit. The views of Rindfleisch will command attention, if not assent, in every particular, and it is not to be expected that his views will command universal acceptance. It is therefore a book more for the practitioner than the beginner, and presupposes some familiarity with the text-books upon the subject. The work of translation has been well done, although we notice some obscurities of expression which might be improved.

THE PHILADELPHIA MEDICAL REGISTER AND DIRECTORY FOR 1884–5. Edited by WILLIAM B. ATKINSON, A.M., M.D. Collins, Printer, 1884.

This well-known physicians' directory, issued under the direct supervision of Dr. Atkinson, preserves its characteristic features which have made it such a useful work of reference in the past, and presents some new ones which enhance its value.

THE *Archives of Medicine* for December contains the editorial announcement of the discontinuance of its publication with the present number, in view of the general preference for periodicals appearing at brief intervals able to furnish scientific material and news with greater promptness. We regret to lose the *Archives* from our exchanges, especially as the last issue contains so much valuable and interesting original material. A general index to the twelve volumes of the *Archives* is also contained in this number.

GLEANINGS FROM EXCHANGES.

Exfoliation of the Cochlea without causing Deafness.—The *Lancet* Vienna correspondent writes: The loss of the cochlea, according to the ingenious researches of Helmholtz, is considered to be equivalent to the loss of hearing-power. A case, however, which Professor Grüber demonstrated on December 12, at the meeting of the Society of Physicians in Vienna, would seem to go far towards refuting this view. The case occurred in a lad aged 14, who had been ailing for four years, and who was admitted into Professor Grüber's wards last November. It was stated that the patient suffered from an old otorrhœa with polypus of the left ear. As the patient experienced great pain, and as paralysis of the left nervus facialis existed, Professor Grüber had no hesitation in entirely removing the polypus, and in doing so came upon the cochlea in a state of necrosis. Since the operation the patient has felt better, his pains have ceased, and the paralysis of the nervus facialis has nearly disappeared; but, strange to say, the lad's affected ear has regained its power not only of recognizing sounds, but of distinguishing musical notes. Only two similar cases would seem to have been recorded. One was observed by Dr. Cassels at Glasgow, the other by Dr. Christinneck in the clinic of Professor Schwarze at Halle. Professor Grüber did not enlarge on the features of this interesting case, but it certainly affords food for suggestive thought in reference to treatment of diseases of the ear. Heretofore the labyrinth was considered a sort of *noli me tangere*, but now we see that the entire cochlea may be missing and yet the aural powers be retained. On the other hand, it is not yet quite certain whether in the above case paralysis of the auditory nerve may not eventually occur.

Tricuspid Stenosis.—In reviewing the general facts of tricuspid stenosis *à propos* of a case of his own, M. Chauffard points out that the only two signs in life we are likely to get of its presence are (1) the existence of extreme venous congestion in the neck without a venous pulse, and (2) presystolic and systolic murmur which culminates over the junction of the xiphoid cartilage with the sternum, and which is by this position and its harshness and superficiality to be distinguished from the murmur of mitral stenosis. With regard to the general conditions of tricuspid stenosis, M. Chauffard is in agreement with nearly all authors,—viz., that it is almost always found in women, in forty-one cases out of forty-six (Fenwick) in adult life, and accompanied by other endocardial lesions, especially by mitral stenosis. In only half the cases does rheumatism seem to have been coexistent; it has been the result of a slow endocarditis, wide-spread and not vegetative, which has glued the bases of the valves together and made them contract. In only one case does it seem to have been congenital. (*Revue de Médecine*, July, 1884).—*Practitioner.*

Trophoneurosis (?) of the Testicle.—A case which may possibly be an example of a trophoneurosis is recorded by M. Lemonnier in *La France Médicale* of December 25. The patient was a young man aged 19, who sustained severe injury to the skull after a fall from a height of about six feet. Hemiplegia of the right side, and rapid atrophy of the testicle and of the right upper limb, are the chief phenomena recorded. There was considerable disturbance of consciousness, but ultimately the patient appears to have recovered to a large extent. The hemiplegia was probably dependent upon compression by blood poured out as the result of the fracture of the base of the skull. No other conditions seem to have been present to account for the rapid wasting of the arm or testicle. Nélaton and others have spoken of the possibility of atrophy of the testicle resulting from causes acting at a distance.—*Lancet.*

MISCELLANY.

Some Recent Decisions on Medico-Legal Matters.—The records of the courts are full of cases of interest to physicians, and a knowledge of them will often be of great value when called upon to appear as parties in actions or as expert witnesses in cases where other persons are litigating. Of the most recent cases the following are of general interest:

In an Indiana court a physician was charged with rape upon the person of a female patient, and the crime seemed to be proved, but the question arose whether the guilty party could not escape the highest penalty because of a possible consent on her part. There was no evidence produced to warrant the claim of a consent. On this point the court said, "If the jury believed, as they might well have done under the evidence, that the appellant as a physician obtained possession and control of Rebecca's person, under her mother's command, for the purpose of making a further examination of her alleged disease of the womb, and not for the purpose of sexual intercourse, and that she never in fact gave her consent, through fraud or otherwise, to the sexual connection, then it seems to us that the appellant was lawfully convicted of the crime of rape." The verdict of the jury was therefore affirmed.

In a Michigan case, the charter of a city obliged the common council to take measures for the preservation of the public health, and

in carrying out this requirement a nurse was employed to attend a smallpox patient. A State law requires patients in the hospitals, if pecuniarily able, to pay for the services rendered them. The nurse faithfully attended to the case, and presented her bill to the city authorities who had hired her. They declined to pay, saying that she must sue the patient. She refused to take this course, but brought suit against the city, and the courts sustained the action and obliged the city to pay. The opinion of the judges on appeal contains the following comment: "Individuals would not be willing to provide necessaries, and serve as nurses and assistants, at the instance of the public, if compelled to collect their pay of the patients or their relatives. The public is first and immediately responsible, and the intent of the statute is to enable the public to obtain reimbursement from those who ought to sustain the expense. The plaintiff hired herself to the city. She trusted the city, and no one else."

In another Michigan case, a tramp was run over by a locomotive in a railroad-yard. A surgeon was summoned to help him, and sent a message to the superintendent and asked if he should do so. The superintendent answered, "Yes." Nothing was said about pay, and, in fact, the superintendent had no authority to bind the railway-company to pay for surgical aid. Under these circumstances the surgeon sued the superintendent, under the theory that he was personally liable. The court held, however, that there was no contract between them of such a character as to make the superintendent liable. The effect of this decision is to exempt both the railway-company and the superintendent from liability, and to oblige the surgeon to look to the tramp for compensation. As "tramps" usually are not men of means, the surgeon probably has been obliged to charge up his services to a general benevolence account.

In a Kansas case, where physicians were called to give expert testimony, the judge charged the jury that such testimony "should be received and weighed with caution," and the question was whether this was a proper direction or not. On this point the court said, "The testimony of experts is to be considered like any other testimony; it is to be tried by the same tests and receive just as much weight and credit as the jury may deem it entitled to when viewed in connection with all the circumstances. We think this is probably as good a general rule as any that could be adopted. . . . While many courts speak disparagingly of some kinds of expert testimony,—that with regard to handwriting, for instance,—yet we think that all courts hold that the testimony of competent medical experts is entitled to great respect and consideration. In the present case, we think the expert testimony of the physicians and surgeons, who were in fact appointed by the court, and who made a personal and professional examination of the plaintiff's eyes, is entitled to great consideration, and that the court below erred when it instructed the jury that such testimony should be 'received and weighed with caution.'"

In Germany the papers report a recent case where a physician used the old methods of treating wounds, instead of the modern antiseptic dressings, and the patient died under circumstances making it probable that if a different treatment had been adopted his life would have been saved. The physician was sued for malpractice, and convicted, the court holding that "every practitioner should keep himself informed on the accomplished progress of science, and have an exact knowledge of modern systems of treatment. If these had been employed, the patient's life might have been saved: hence the liability for negligence."

Life-Saving from Drowning by Self-Inflation.—Dr. Henry R. Silvester (*Lancet*) makes the ingenious suggestion that the inflation of the cellular tissue of the upper part of the body can be accomplished by making an opening in the mucous membrane, at the junction of the gums and cheek, with a knife or sharp piece of wood, and then filling the mouth with air and blowing it forcibly through the opening into the fascia. Sufficient inflation can be obtained in three minutes to support the body in the water.

The Annual Meeting of the Medical Jurisprudence Society was held January 13. The following officers were elected for the ensuing year:

President.—George W. Biddle, Esq.

Vice-Presidents.—John J. Reese, M.D., and William N. Ashman, Esq.

Recorder.—J. Solis Cohen, M.D.

Secretary.—Henry Leffmann, M.D.

Treasurer.—Hampton L. Carson, Esq.

Burning of an Insane Asylum.—The daily papers contain an account of another horrible calamity, the burning of the Illinois State Insane Asylum at Kankakee on the 17th instant, in which some twenty unfortunate patients perished. The newspaper report blames the Legislature for the niggardly appropriations, which prevented the proper safeguards and fire-escapes from being provided.

The County Medical Society gave a reception in honor of the retiring President, Dr. William M. Welch, on the 14th instant, on which occasion Dr. Welch read a valuable report upon the early history of vaccination in this country as his annual address.

A Good Appointment.—Dr. Edward N. Brush, of the Utica Asylum, and formerly of Buffalo, has been appointed Assistant Physician in Charge of the Male Insane Department of the Pennsylvania Hospital.

NOTES AND QUERIES.

AN OLD FORM WHICH MIGHT WELL BE REVIVED.—To the kindness of Prof. Osler we owe the following copy of an indenture which was in use in the early part of the century in England, and which seems of sufficient interest to warrant publication. We commend it to the State Medical Society.

"*This Indenture Witnesseth*, That Edward O——, of the town of Falmouth, in the county of Cornwall, by and with the consent of his Father, doth put himself Apprentice to James X., of said town of Falmouth, Surgeon, to learn his Art, and with him, after the Manner of an Apprentice, to serve from the 2nd day of March, Eighteen hundred and Eleven, the full End and term of five years from thence next following, to be fully complete and ended.

"*During* which term the said Apprentice his Master faithfully will serve, his secrets keep, his lawful commands everywhere gladly do. He shall do no damage to his said Master, nor see to be done of others, but to his Power shall let or forthwith give warning to his Master of the same. He shall not waste the Goods of his said Master, nor lend them unlawfully to any; he shall not commit fornication nor contract Matrimony within the said term. He shall not play at Cards or Dice-Tables, or any other unlawful Games whereby his said Master may have any loss with his own goods or others during the said term, without the license of his said Master. He shall neither buy nor sell; he shall not haunt Taverns nor Play-houses, nor absent himself from his said Master's Service day or night unlawfully, but in all things as a faithful apprentice he shall behave himself towards his said Master and all his during the said term.

"And the said James X., for and in consideration of the sum of forty pounds lawful money of Great Britain, one moiety of which to him in hand paid, the other moiety when half the term is complete, the said Apprentice in the Art of Surgery and Physic which he useth by the best means that he can shall teach and instruct or cause to be taught and instructed. Finding unto the said Apprentice sufficient meat, drink, lodging, and all other necessaries during the said term.

"And for the true performance of all and every the said Covenants and Agreements, either of the said Parties bindeth himself unto the Other by these Presents.

"In witness whereof, the parties above named to these Indentures interchangeably have put their hands and seals this 22d day of March, and in the fifty-first year of our Sovereign Lord George III., by the Grace of God of the United Kingdom of Great Britain and Ireland King, Defender of the Faith, and in the Year of our Lord one thousand eight hundred and eleven.

"Signed, sealed, and delivered in the presence of
"I. GRIFFIN."

Three-penny stamp (on the paper).
One pound ten shilling stamp (to the indenture).

OBITUARY.

BENJAMIN FRANCIS SILLIMAN, M.D.—At his residence in New Haven, Prof. Silliman died on the 14th inst., of heart-failure, consequent upon progressive cardiac lesion. One of the most honored pioneers of American science, his labors in connection with the Scientific School of Yale College, which owed its inception to his energy and enthusiasm, and his share in the establishment of the National Academy of Medicine, have rendered him eminent in the annals of science in this country, while his contributions to literature have made his name familiar as household words.

Born in New Haven in 1816, he entered Yale in 1833, and was graduated in 1837. Soon afterwards he fitted up a laboratory for instruction in analytical chemistry and mineralogy, which was afterwards developed into the Yale Scientific School, recognized and adopted as a fourth department of Yale College by the authorities in 1847. In 1845 Dr. Silliman delivered what was probably the first series of lectures on agricultural chemistry in the United States, and in 1849 he was called to the Medical Department of Louisville University, in which he took the chair of Medical Chemistry and Toxicology. It was here that he formed a friendship with Prof. Gross which continued through life. He was one of the guests at the dinner given to Prof. Gross by the profession of this city in honor of his completion of the fifty-first year of the practice of medicine.

In 1854, Prof. Silliman, leaving Louisville, returned to New Haven to accept the chair of Chemistry in the Academical and Medical Departments of Yale College, in which he was the successor of his father. His collection of mineralogical specimens, obtained by him in his early travels across the continent and subsequently enriched by careful selection, was presented by him to Cornell University in 1868.

Dr. Silliman's works, The First Principles of Physics and of Chemistry, were adopted by schools all over the country, and are still valued as text-books, while his editorial labors in connection with the *American Journal of Science and Arts*, as well as his many papers on scientific subjects, have left an indelible impression upon American science. He received the honorary degree of M.D. from the University of Charleston, South Carolina, in 1849.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 4, 1885, TO JANUARY 17, 1885.

HEAD, JOHN F., COLONEL AND SURGEON.—Retired from active service by operation of law on January 9, 1885, under provisions of Act of Congress approved June 30, 1882. S. O. 7, A. G. O., January 9, 1885.

PROMOTIONS.

LIEUTENANT-COLONEL JOHN CAMPBELL, SURGEON.—To be Surgeon, with rank of Colonel, December 7, 1884.

MAJOR R. H. ALEXANDER, SURGEON.—To be Surgeon, with rank of Lieutenant-Colonel, December 7, 1884.

CAPTAIN HENRY MCELDERRY, ASSISTANT-SURGEON.—To be Surgeon, with rank of Major, December 7, 1884.

APPOINTMENT.

JEFFERSON R. KEAN.—To be Assistant-Surgeon, with rank of First-Lieutenant, December 8, 1884.

MCKEE, J. C., MAJOR AND SURGEON.—Ordinary leave of absence still further extended four months, on surgeon's certificate of disability. S. O. 6, A. G. O., January 8, 1885.

BENTLEY, EDWIN, MAJOR AND SURGEON.—Leave of absence extended two months. S. O. 8, A. G. O., January 10, 1885.

TREMAINE, W. S., MAJOR AND SURGEON.—Relieved from duty at Fort Porter, New York.

GIRARD, A. C., CAPTAIN AND ASSISTANT-SURGEON.—Ordered for duty at Fort Porter, New York.

APPEL, D. M., CAPTAIN AND ASSISTANT-SURGEON.—Ordered for duty at Plattsburg Barracks, New York.

GIRARD, J. B., CAPTAIN AND ASSISTANT-SURGEON.—Ordered for duty as post-surgeon, Fort Schuyler, New York Harbor.

HAVARD, VALERY, CAPTAIN AND ASSISTANT-SURGEON.—On being relieved at Fort Schuyler, authorized to avail himself of leave of absence (four months).
S. O. 8, Department of the East, January 12, 1885.

ELBREY, F. H., CAPTAIN AND ASSISTANT-SURGEON.—Sick-leave still further extended six months, on surgeon's certificate of disability. S. O. 9, A. G. O., January 12, 1885.

SHANNON, WILLIAM C., CAPTAIN AND ASSISTANT-SURGEON.—Relieved from duty at Fort Bridger, Wyoming, and assigned as attending surgeon at Headquarters Department of the Platte. S. O. 2, Department of the Platte, January 5, 1885.

ROBINSON, S. Q., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to temporary duty at Portland, Oregon, from December 17, 1884. S. O. 206, Department of the Columbia, December 22, 1884.

APPEL, A. H., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for one month, to take effect on or about January 7, 1885 (Madison Barracks, New York). S. O. 268, Department of the East, December 31, 1884.

WALES, P. G., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Vancouver Barracks, Washington Territory, and ordered to return to his proper station, Fort Cœur d'Alène, Idaho. S. O. 204, Department of the Columbia, December 19, 1884.

LIST OF CHANGES OF STATIONS OF NAVAL MEDICAL OFFICERS FROM JANUARY 3, 1885, TO JANUARY 10, 1885.

Surgeon J. W. Ross, detached from the "Monongahela," for treatment at Naval Hospital, New York.

P. A. Surgeon HOWARD WELLS, detached from Naval Hospital, Philadelphia, Pa., to the "Monongahela."

PHILADELPHIA MEDICAL TIMES.

PHILADELPHIA, FEBRUARY 7, 1885.

ORIGINAL LECTURES.

CLINICAL LECTURE
ON THE REACTIONS OF DEGENERATION.

Delivered before the Fourth-Year Class of the University of Pennsylvania

BY JAMES HENDRIE LLOYD, M.D.,

Instructor in Electro-Therapeutics in the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M.D.

GENTLEMEN,—I wish to-day to review in part the subject over which we have already gone, and to still further enlarge upon the law of electrical reactions. These are really the foundation of the science of electro-therapeutics. The names of Erb and Brenner in Germany are especially identified with this subject, while De Watteville in England has written the most lucid explanation of these reactions.

The first subject to be considered is the phenomenon known as electrotonus. Electrotonus refers to the condition into which a nerve passes upon having applied to it the poles of a battery. In this condition the nerve is found, under the cathode or negative pole, to become very much increased in its irritability, while under the anode or positive pole its irritability is lessened. In other words, the cathode or negative pole is an irritating agent, and the anode or positive pole is a depressing agent. It is still further found that on the removal of the anode there is then a slight increase of the irritability. Where formerly there has been depression there is a rebound or recoil, causing an increase of irritability.

When I speak of any agent as being irritating to a motor nerve, it is to be understood that that irritation is exhibited by movement of the muscle to which the nerve is supplied. My present remarks apply to nerves as found in the physiological laboratory, isolated from all surrounding tissues. The portion of nerve between the two poles, provided the poles are applied at some distance from each other, is neutral, and this is an important fact to remember. It is only under the poles that this change in irritability is observed, this being exhibited under certain conditions by contraction of the muscular tissue to which the nerve is distributed. To put the subject in a concise and epigrammatic form, a recent writer has said, "The nerve is aroused in passing from a lower to a higher state of excitability."

It was formerly the custom of physiologists and also of therapeutists to regard altogether the *direction* of the current in their experiments and applications to disease: the direction was made all-important. When the current was passed downward in the direction of the nerve it was called the direct current, and when it was passed up the nerve the inverse current. The difficulty was that the subject became so involved in contradictions and such diverse results were obtained that it was difficult to elaborate any satisfactory law from this mass of contradictory facts. Under these circumstances it remained for Pflüger to elaborate from this confusion a systematized law, to which we shall come in due course of time. In the mean time we can again return to the fact that it is not the direction of the current, for, as I have said, the portion of nerve between the two poles is unaffected unless the poles are brought so close together that their mutual influences overlap. This shows that it is not the direction of the current which causes the excitation of the nerve, but that it is what is called the polar influence, possibly due to molecular change occurring under the individual electrodes, which causes muscular contraction as the nerve passes from a lower to a higher excitation.

It will not be necessary for me to go into all the details of the demonstration of Pflüger, but from his experiments and observations he was enabled to elaborate a series of laws, the whole point of which is simply this: That the phenomena displayed in the muscular tissue by contraction, and the condition of irritation of the nerves, depend not on the direction of the current, but (1) upon the pole whose influence is felt, (2) upon the strength of the current, and (3) upon the fact whether the current is made or broken. These are the three elements of the proposition. These results are constant and always capable of application, whereas in the old time one physiologist or therapeutist would assert that the descending current was the one to be used in order to produce certain

effects, while another would assert that the ascending current was the proper one to be applied under such circumstances.

I have told you, when speaking of electrotonus, that when a nerve is under the influence of an electric current its excitability is increased at the negative pole and depressed at the positive pole. The result of this is that the first stage of excitability which we have in a nerve, according to the laws of electrotonus and of Pflüger, results from the closure of the cathode, for this is simply saying that an exciting agent is applied to the nerve, just as though it were stuck with a pin or touched with a hot iron. The cathode raises the nerve from a lower to a higher state of irritability. The mildest current which will produce any reaction is that which first causes contraction at the closure of the cathode. This is expressed as follows: Ca C C, in which Ca stands for cathode, C for closure, and the second C for contraction.

What would be the second natural deduction from the laws of electrotonus and from Pflüger's observations? The nerve is excited in passing from a lower to a higher state of irritability. The anode depresses excitability, and therefore applying the anode will not cause contraction, but rather the reverse,—*i.e.*, it puts the nerve in a condition in which it is not so readily excited. If, however, the anode is applied for a minute and then taken away, there will be a rebound from the lower to a higher state of excitability, so that the second reaction, which, however, is not so strong as the cathodal closure, is anodal opening contraction. It is thus expressed: An O C. Bear in mind that I am still speaking of physiological experiments where the nerve is isolated from surrounding tissues.

The next reaction which we have will require a little further demonstration. According to the laws of Dubois-Raymond, the reaction of a nerve to electricity depends not only upon its passing from a lower to higher excitability, but also upon changes in the density of the current: that is, it is not caused by the absolute amount of electricity passing through the nerve at any particular moment (*i.e.*, the absolute density), but it is caused by the change of density of that current from one moment to another. For instance, take a strong current running through a nerve, and take a second nerve under the same circumstances and transmit a mild current through it. There will be no reaction in either case while the currents are running. If, however, the current is made or broken, the density of the current is rapidly changed and reaction is produced. It is not the strength of the current so much as the sudden changes in strength which causes the reaction. A mild current passing through the nerve produces no reaction, but if the current is suddenly increased a reaction is produced.

Let us now consider the application of the current to the nerve under ordinary circumstances, for instance, as found in the arm of a man, covered with skin, fat, fascia, blood, and muscular tissue,—these being more or less good conductors, some of them, as the blood, being even better conductors than the nerve itself. It is impossible in applying electricity under such circumstances to so apply it that the current will be completely confined to the nerve-trunk. In other words, there is diffusion of the current from the electrodes, much of it, however, striking the nerve and passing through it *transversely* in a fan-like shape. You recall what it is that makes the positive and the negative poles. That is the positive where the electricity first impinges upon the nerve, and that is the negative where it leaves the nerve. The result of this is that under every electrode we have in the nerve not only the electricity represented by the sign of that particular electrode, but also the electricity of the opposite sign. We have also to recollect another condition. According to the law of Dubois-Raymond, it is the difference in density which determines the muscular contraction. Now, in the case supposed, the electricity from the positive pole flows into the nerve in a comparatively narrow stream. Where it enters the nerve it is dense. Where it leaves the nerve it does so in a fan shape, and is less dense. The electricity which enters the nerve immediately under the electrode is termed the actual pole by De Watteville, and has much the greatest density, while that which leaves the nerve is termed the virtual pole, and has much less density.

I have told you that the strongest reaction was produced by closure of the cathode, and that the next strongest was produced by opening of the anode, because in both the same thing was produced: the nerve passed from a lower to a higher

state of excitability. What, however, do we find in actual experience when electricity is applied to a patient? We find that we do get the strongest result from cathodal closure, but by no means always the next strongest reaction from anodal opening. The anodal *closure* contraction is quite as strong as that of anodal opening. How is this apparent contradiction to be explained? With anodal closure we get quite a strong contraction, and yet we know that the anode causes depression of excitability. The explanation is as follows: When we make anodal closure we get really not anodal closure, but we get the influence of the cathode which is exerted on the *opposite side* of the nerve, or in what De Watteville calls the *peripolar* area. It is exerted where the density is much less, where the electricity is leaving the nerve. The consequence is that you have the cathode acting under anodal closure, but acting under a disadvantage, and as a result it does not give as strong a contraction as with the cathode on the skin. The peri-polar zone probably does not represent more than one-fourth the density. In illustrating this point a simple mathematical problem, somewhat after the manner of Erb, may be made use of. Ca is taken as equal to 4, the anode as equal to 2. The polar zone, *or near side*, where the electricity is much denser, equals 4, while the peri-polar zone, where the electricity is less dense, equals 1. The terms of the formula are therefore as follows:

Ca = 4.
An = 2.
Pz = 4.
pPz = 1.

If the cathode is acting in the polar zone, the formula is $4 + 4 = 8$: that is, the density added to the excitant. If, however, the anode is acting in the peripolar zone, then $2 + 1 = 3$. These figures do not indicate the relative intensity, but are simply used for the purposes of illustration.

It is these demonstrations which enable us to understand many things about electrical reaction. They enable us to understand why it is that we get any contraction by closure of the anode. It is because we really have the cathode acting in the peripolar zone, or the virtual cathode instead of the actual anode.

The last contraction which we have is from opening of the cathode, represented by Ca O C. The cathode being an irritant, it is difficult to understand why taking it off should produce a contraction. It is easy to see how applying an irritant will cause contraction, but it is not so easy to see how the removal of an irritant will also produce contraction. It is only with a strong current that this can be obtained. The fact is that under these circumstances the cathode is not acting, but that you have an anodal opening in the peri-polar zone. It is of course acting at a great disadvantage, and the contraction is very slight, even with currents which are almost unbearable.

This is about all the demonstration which it will be necessary to give of the laws of electrical reaction, but I wish to give one illustration of their value. If you place the electrode on the median nerve, for instance, and make cathodal closure, there will be contraction of a certain set of muscles. Now, if anodal closure be made, you will possibly see a different set of muscles move, although the electrode has not been moved. The explanation of this is that, in the first instance, the cathode is acting in the polar zone, and consequently the upper fibres are especially affected. In the second instance, when anodal closure is made it is really a virtual cathodal closure, the cathode acting in the peri-polar zone, and a different set of nerve-fibres are irritated and a different group of muscles are thrown into contraction.

Take, for example, what are known as voltaic alternatives. If you have the electrode upon the nerve-trunk and break and make the current, you will find that you have the customary reaction; but if instead of simply making and breaking the current you suddenly swing it from anode to cathode, a much stronger reaction is obtained. Why is this? Suppose the current is passing and the anode is acting in the polar zone. Then you instantly change to the cathode, which will also act in the polar zone, so that you get anodal opening added to cathodal closure, and, of course, an increased effect. There are many other problems which can be worked out by these same formulæ.

I wish next to refer to pathology to show wherein these reactions are of value. Almost identical results are obtained whether the electrode is applied to the

nerve-trunk or to the muscular tissue. Changes in these formulæ are only obtained when there are changes in the nerve-trunks or in the anterior cornua of the spinal cord. When there is a pathological change, resulting perhaps from traumatism, the nerve becomes degenerated and may be gradually reduced to the condition of a mere fibrous string. Under these circumstances especially we get modifications of these reactions. These changes are also obtained in anterior polio-myelitis, which is characterized by an increase of the connective tissue which presses upon and blots out the cell-elements of the anterior cornua. We do not get changes in these formulæ when there is paralysis due to brain-lesion. In a case of embolism of the middle cerebral artery or of a clot in the ventricle, none of these reactions are obtained,—at least not for a long time, and then only when descending sclerosis affects the anterior cornua. Changes in these formulæ are therefore significant of changes in the anterior cornua, in the nerve-trunks, or in the muscular tissue.

To be brief, these changes may be said to be a diminution in cathodal closure and an increase in anodal closure, so that the anodal closure may excel the cathodal closure in the power of causing contraction. Why the virtual cathode in these pathological changes excels the actual cathode has, as far as I am aware, never been satisfactorily explained. Cathodal opening contraction is also increased. The character of the contraction also changes; instead of the usual quick response the muscle contracts slowly, and with a prolonged effort.

I wish also to say that these changes are not so invariably present that you may expect to find them in all cases of peripheral palsies. I will show you cases to-day which I have brought here not because I can show these changes, but because I can *not* show them. This simply demonstrates the fact that, no matter what the books may say, in many of these cases the changes are slight or wanting. If they are present they have positive value, but their absence is not always of great negative value. Some fibres may escape and carry the impulse. There may also be a degree of improvement which will obscure the reactions of degeneration which had been found on a previous occasion. While we cannot always explain this satisfactorily, we still have the fact that the reactions of degeneration are not so constant as some would have us believe.

I wish to also state that the first signs of degeneration are not only the qualitative signs of increase of the anodal closure over the cathodal closure, and after a time even cathodal opening contraction, but also the *quantitative* changes. This means that the whole excitability of the nerve to galvanism is at first increased. It is not, as would naturally be supposed, decreased, but increased. After the increased excitability has diminished and is passing on to decreased excitability, the qualitative changes appear. This may be the reason that we cannot always elicit the qualitative changes. The nerve may have been injured only sufficiently to produce the quantitative changes, and under curative measures or the remedial force of nature it has recovered before the degeneration has gone sufficiently far to produce qualitative changes.

I shall now ask your attention to some of the cases which I have here. This first case is one of lead-palsy. I do not intend to enter into any speculations as to the nature of lead-palsy. It is sufficient to know that lead-poisoning usually causes paralysis of the extensor muscles of the forearm. This man is improving, and the reactions of degeneration are not as marked as they previously were. In order to excite the extensor muscle of the forearm we must, of course, apply the electrode over the trunk of the musculo-spiral nerve, which will be found midway between the bend of the elbow and the insertion of the deltoid muscle. This is called the *active* electrode. The other, or *indifferent* electrode, we place at a distance on patient's body,—usually on back of neck or over the sternum. If this man exhibits any of the reactions of degeneration, we should expect that the anodal closure would be as strong as, or stronger than, the cathodal closure. I first make cathodal closure, and a very slight reaction is obtained. I next try anodal closure. The contraction produced is at least equal to that produced by cathodal closure. It should be decidedly less in health. I next try the effect of anodal opening. In order to practise this it is well to allow the current to pass through the nerve for a short time, in order to get the trunk into a condition

of anelectrotonus, or a condition of depressed excitability. Making anodal opening, I obtain no contraction. Applying the electrode to the radial nerve, we find that the contraction from anodal closure is decidedly stronger than that from cathodal closure. This man has passed beyond the time in which there is a quantitative increase in the excitability, and it takes a strong current to affect him. The current which I have used was forty cells of the modified Leclanché battery.

In applying electricity in this way, you should always begin with the mildest possible current which will produce response from cathodal closure. This is to be tried first. Eight or ten cells are usually sufficient for this, and then the current is to be increased by the addition of two cells at a time until anodal opening or anodal closure contraction is elicited.

This second case is a very rare one. It is apparently a case of lead-poisoning in which the lead has not sought its usual area of devastation, but has first affected the deltoid muscles, and is now involving the muscles of the thigh. This is a recent case, and has hardly progressed far enough to give the reactions of degeneration. There is a slight reaction to cathodal closure. Anodal closure seems to be as strong as, and possibly a little stronger than, cathodal closure contraction.

The next case is one of unilateral wrist-drop. When we find this we may be almost sure that the man has been sleeping with his head on his arm; but a man rarely or never sleeps long enough on his arm to produce wrist-paralysis, unless he has been indulging in ardent spirits. This wrist-drop is due to pressure on the musculo-spiral or radial nerve. In this case there have been no qualitative signs, and this is a good indication. There are, however, quantitative signs. The anodal closure contraction is much less than the cathodal closure contraction. I shall next try to obtain an anodal opening contraction. I have tried this in many cases, and have come to the conclusion that anodal opening contraction is by no means as prominent as the books state. There is slight reaction, but that cannot be called a change in quality. I next try these reactions on the well arm, and we find that they are much *less* marked on the sound than on the affected side; hence there is a decided quantitative change.

This is another case of unilateral paralysis due to the same cause as was the previous case. In this case, however, the median nerve was pressed upon, leading to paralysis of the flexor muscles. This is also a recent case. I apply the electrode at the bend of the elbow over the median nerve. There is, as you see, some degeneration reaction.

The last case which I show you is one of peripheral palsy, the nature of which is somewhat obscure. It is supposed to be a case of anterior polio-myelitis. It came on after some severe exertion in the use of the arms. The muscles of the ulnar distribution are the ones affected. This case has given some few reactions of degeneration. With twenty-two cells we obtain cathodal closure contraction which is more marked than anodal closure contraction, but, as I have said, at one observation we often obtain different results than at a former trial. On a former occasion the muscles of the ulnar distribution gave an increase of anodal closure over cathodal closure contraction.

I may say, in conclusion, that the best interrupter to use for these investigations is one attached to the handle of the active electrode, and under control of one finger.

ORIGINAL COMMUNICATIONS.

THE WESTERN HEALTH-SECTION.

BY W. THORNTON PARKER, M.D.
(MUNICH).

A RECENT article of mine in the *Archives of Medicine*, concerning the climate of New Mexico,* has brought me several letters from Western physicians, somewhat severely criticising my opinions concerning that country. A few physicians, especially one in Denver, have kindly sustained my views, and appreciated the difficulties attending any medical man who tries to explain the conditions obtaining at a famous health-resort.

Two articles have appeared within the year in the *Medical Times*,—"The Southwest as a Health-Resort," by Dr. H. C. Wood,† and "The Northwest as a Health-Resort," by Dr. J. J. Leeser,‡—and Dr. S. A. Fisk has contributed a communica-

* Concerning the Climate of New Mexico. Archives of Medicine, October, 1884.
† Philadelphia Medical Times, October 6, 1883.
‡ Ibid., January 26, 1884.

tion on "The Climate of Colorado" in the *New York Medical Record*.* These three articles go very far to prove that the day has passed by for medical men to commend for pulmonary diseases a "humid mild climate." Such a climate cannot *cure*, even if it be able to mitigate, the miseries of pulmonary diseases.

Looking at the map of the West, we find a section of country bounded on the south by lat. 30° N., on the west by the Rocky Mountains, on the east by long. 100° W., and running northward as far as civilization extends. In this section we have the *best* opportunities, to my thinking, for the *cure* of what is popularly known as consumption, to be found perhaps in the whole world; and here, if anywhere, will be found *the atmosphere* which is most desirable.

Considering the evidence offered us in recent medical literature, not excepting the teachings of Prof. Loomis and others in standard medical works,† we must admit that, in general, *dryness*, either cold or mild, is the most desirable condition sought for, other things being equal, in the treatment of pulmonary diseases. Elevation is not so desirable as dryness, and I believe, with others, that it may destroy the good results obtained or obtainable by living in a dry climate. Equability is too often confounded with mildness, and is hard to find. In the northern climates we have a steady winter, and, where out-of-door life can be enjoyed, this is a valuable aid in the "cure."

A great mistake is often made in mapping out sections as *desirable*. In drawing the lines of the imaginary section just described, I have said that *in* this section we have the *best* opportunities for the cure of consumption; but I do not claim that *every* square mile of this health-giving tract might contain a sanitarium, by any means. Journeying about the Rockies, the climate will be found very changeable, presenting every kind of exposure and protection, with even some sections quite moist and malarious, others dry and yet poisoned by unhealthy air. Besides all this, opportunities for the most ordinary comforts, and even safety, of life, are lacking in many districts, while they abound in others. But, taking this division in general, we can confide pulmonary patients there with considerable hope, provided they have the means and the courageous will to get well.

Dr. Wood claims that "where warmth and dryness are associated, the conditions are most favorable." Dr. Leeser stoutly maintains, on the other hand, that where clear cold weather and dryness are associated, the conditions are most favorable. Here, then, we can see the end of doubts. Depend upon it, we are nearing a solution of the problem, even if it be the old story repeated of the shield of two colors.

I have said that the overwhelming evidence, as well as practical experience, teaches that *dryness* is the main chance for cure. Leaving New Mexico in the middle of October and coming swiftly East, although in the midst of an unusually *dry* season, I found the change tremendous, and when at last I reached this "city by the sea," as it has been poetically (?) termed, nature rebelled, and a sharp illness followed. In the experience just detailed it is seen how great is the risk in coming down from 6700 feet above (the altitude of Fort Union, New Mexico) to the sea-level; but often we can ascend from an altitude of say 6000 feet to 8500, yet suffer from humidity! During the month of September I was ordered from Fort Union, New Mexico (6700 feet), to Fort Lewis, Colorado (8500 feet), *but on the Pacific slope*. I felt the change from a dry mild climate to a moist chilly climate very severely, and a winter in such a climate would have been a very undesirable experience. A severe attack of broncho-pneumonia in May had left my lungs in a very sensitive condition, and I was slowly regaining health when this exposure to the climate of the Pacific slope seriously threatened sickness, and a longer residence would have undoubtedly proved seriously injurious, to say the least.

The section of country west of the Rockies, comprising what is known as the "Pacific slope," is in my opinion very undesirable. Colorado between Pueblo and Denver, and some places north, contain the most desirable health-resorts at present within reach, and it would be hard to rival the glorious scenery and life-giving atmosphere of Colorado Springs and Manitou. Penetrating southward of Pueblo, I can speak highly of Trinidad, Colorado, and within a few years, if the better class of citizens is permitted to carry out its plans

* New York Medical Record, November 8, 1884.
† Vide Loomis's Practical Medicine, page 206.

for reforming and improving the town, a delightful and accessible health-resort will there be found.

Moving still farther southward, we pass through a beautiful section of country, now devoted to cattle-raising. As we look out of the cars in the early morning, it seems as if we had entered some wonder-land, slumbering, as it were, in all its native beauty, before the arrival of the thousands who would gladly possess it, if the curse of land-grants and dishonest "rings" could be removed.

Continuing on our way, Las Vegas is reached, and, save for a visit to the "Springs," can be left behind. The Springs are beautifully situated, and when the hotel is finished they will be quite a resort, no doubt, but always inferior to Manitou unless great changes occur in this Territory. In New Mexico, three points besides the Springs can be recommended to invalids desiring moderate elevation, dryness, and equability: they are Santa Fé, Albuquerque, and Silver City, and in their desirability as residences for invalids I think they stand in the order named.

Since writing my former article on the climate of New Mexico, I have been inclined to bring to the notice of the profession the many advantages possessed by Albuquerque. It is undoubtedly true that much that is bad and undesirable, and even violent, exists in that "city of the hard name;" but it is improving steadily. A good class of citizens is already on the ground, and positively excellent society is already to be found, with good schools, churches, stores, etc., and also well-built houses at fair rental. It is somewhat warmer than Santa Fé, and, though not so interesting, is quite as healthy. For those who desire "everlasting summer," as the climate of southern New Mexico has been called, Silver City—bright and shining as its name would imply—offers health and a fair prospect of *wealth* with patient effort.

The climate of New Mexico is "mild and dry," but its elevation, if acceptable and agreeable, must be taken for life. Change from New Mexico eastward to the Atlantic or westward to the Pacific is not advisable, and in the case of the invalid is dangerous. The longer the stay the *greater* the risk. The climate, after one is accustomed to it, slowly but surely winds its confining coils around one, and if experienced for any length of time cannot recklessly be exchanged for a lower and moister level. The effect on the system seems to be a gradual thinning of the blood and general enervation, amounting in some cases to feelings of general debility, indolence, and languor. It seems very risky for patients afflicted with heart-troubles to be sent to an elevation of over four thousand feet above sea-level, if even that much can with safety be endured. It is the climate, to a certain extent, which accounts for the sleepy, worthless feeling which so many complain of.

Great caution is necessary with regard to food. Coffee and arterial stimulants generally must be diminished, and meats should be used sparingly, vegetables, bread, and milk being used more as substitutes. Amongst the population coarse bread, corn-meal, eggs, chicken, and much "red pepper" are used for food, and a short residence in the country explains it all. The torments of the land are the frequent dust-storms, which dishearten and fairly sicken one. These occur principally in the winter and spring. During the prevalence of these storms one must stay in the house, and even then the dust covers everything and makes life, at best, "horrid." Meat and vegetables are poor and comparatively expensive. The pleasant side of the picture is the *constant bright sunshine* and clear skies, and glorious mornings and evenings. Many nights I have spent sleeping on the ground, the clear skies, star-filled, for canopy, and the delicious atmosphere refreshing and invigorating the body. Little dew falls, and one wakes in the morning after such a rest, refreshed and cheered. In what a strong contrast is life within "adobe" houses! The air is so light that windows must be left open, even at the risk of draughts, and unless particular to have a plentiful supply of air—which is not always possible—one awakens fatigued and weary. The rainy season is in the summer, but this is not objectionable. The showers come in the afternoon, refreshing all nature, and they are soon over, and do not keep one in-doors very long. The nights are cool, and there is little if any annoyance from mosquitoes. The study of New Mexican climate, to a visitor, is simply bewildering. A series of maddening contradictions are discovered, in which there is much to admire and much to deplore.

Since my return I notice a tendency for blessings to brighten as they take their

flight; but, in view of the fact that Colorado, Wyoming, Dakota, and Montana are improving in their accommodations for invalids each day, and offering, in my opinion, more certain and more pleasant sanitariums than New Mexico ever can hope to do, I should prefer (all things considered) to recommend patients North rather than South. It depends very much upon who is to be sent. For a nervous, feeble invalid, Santa Fé or Albuquerque might be better, but for a young man of good spirits, with some hope still left, I should urge Colorado or Montana.

In the rush West we are liable to lose sight of many healthy places in Iowa, Minnesota, Nebraska, and Western Kansas. In the admirable paper of Dr. Wood no mention is made of the "Pan-handle" of Texas,—that section of country between New Mexico and the Indian Territory. The climate there is well described by Dr. Wood, and its excellent condition may be known to Dr. Loomis when he speaks of "the extraordinarily dry belt of country which runs northward from San Antonio, Texas,"—the "home of the cowboy," as the tract is called running northward to Kansas through the "Pan-handle." Towns are scarce, but not so wild and disagreeable as one would imagine. After leaving the railroad at Dodge City it is a ride of two hundred miles to Mobeetie, the first town of the Pan-handle.

I do not think that the plan of "roughing it" is a practical one for invalids, or to those inexperienced in camping out, and there is too much danger and hardship to make many men desire it very much; although I certainly do believe that to get well camping is the very best way in which to live for health's sake. Nothing is better in summer than the canvas house well built and well arranged, and equipped with that indispensable adjunct,—the most important member of the party,—a really good cook. Plenty of nutritious food must follow the abundant exercise and exposure to the fresh air, and a small allowance of books is quite necessary for mental food. And here comes in the question of tobacco. To those who love the delicious plant it will be a comfort to turn to the appreciative yet temperate comment upon the "weed" contained in the "United States Dispensatory:" "Moderately taken, it quiets restlessness, calms mental and corporeal inquietude, and produces a state of general languor or repose which has great charms for those habituated to the impression. . . . It must have properties peculiarly adapted to the propensities of our nature to have thus surmounted the first repugnance to its odor and taste and to have become the passion of so many millions." Is not this authority great and good enough to stop us from taking the pipe and the delicious "Durham," or any other tobacco, from our patients? Undoubtedly its loss is depressing to the mind and adds discouragement, in that the lover of the pipe, deprived of his solace, is forced to believe that he must be either very sick to be ordered to do without it, or else that he must be feeble if a return to it would be dangerous. I have met many who have had their tobacco-supply ordered stopped by their medical advisers, but found no evil results following a return to the fragrant pipe; on the contrary, sometimes a commencing habit of constipation was thereby arrested. The importance of this reference to tobacco-smoking cannot fail to be recognized, and the digression will be pardoned by those of my readers who are old smokers.

The weight of a folding cot is not much addition to the luggage, but its comfort in camp is worth a great deal. Some scorn the cot as being incompatible with true camping, but, when we consider perils by rattlesnakes and the deadly Western skunk, those who take Dr. Wood's prescription of roughing it will do well to have with them, and for use, a comfortable, strong, folding cot.

In conclusion, I think that we should not forget to properly estimate the importance of increased altitude as a possible source of disease, and guard our patients accordingly. I believe that the altitude and the dust-storms, the cheerless, damp adobe houses, and the poor food and the depressing social (or unsocial) life, are strong arguments against sending patients, and particularly very sick patients, south of Trinidad, Colorado. The country as a sanitarium has been overestimated; and yet there is much, in spite of all I have said against the climate, to encourage one to hope for some relief in cases of early phthisis, if not a positive cure, provided that the sick one has the double protection of a full purse and a careful attendant. It is no place for a *poor* invalid: even the

rich will find it expensive enough. There is little to suggest exercise in New Mexico. A listlessness overhangs all life, and one longs to see something besides the mud and mud walls, the dust-storm, and the sky. The mountains and the sunshine help, but do not entirely atone for all we have left behind us. The trip for all is a lottery; for some are prizes of gold, for others health, and these prizes may bring happiness, although they must be enjoyed where they are found; but for many, very many, is a hastened death, or such loneliness that death itself may be regarded as a relief.

The question is asked, "Is not the climate of New Mexico better than we can find in most of the States east of the Mississippi River?" I do not hesitate to declare that it is. However, let the physician beware how he hurries his patient away from home-comforts and friends; let him carefully study different sections of country, so as to know and understand them, and to be able to tell his patient what he can reasonably expect when he reaches a given place. Personal experience, after all, is better than studying the roseate-hued pen-pictures of health-resorts and railroad books of travel. Physicians should investigate for themselves, in order that invalids may be wisely directed. To study climatology without travelling is like studying anatomy without dissecting, and he who recommends resorts which he has not seen and examined may be the means of making much unhappiness.

Atlantic City, N.J., December 30, 1884.

REPORT ON THE PROGRESS OF OTOLOGY.

BY CHARLES H. BURNETT, M.D.,
Philadelphia.

SYPHILIS OF THE EAR.

DR. JÉGU (*Annales des Maladies de l'Oreille*, etc., Mai, 1884), in a graduating thesis, treats of syphilis of the ear under two grand divisions of acquired and hereditary disease. His conclusions respecting acquired syphilis of the ear are, first, concerning the external ear,—viz.:

1. A syphilitic chancre is found in the external ear only as a very rare exception.

2. Secondary manifestations are of greater or less interest according to their situation upon the auricle or in the auditory canal. Syphilides of the auricle are not specially distinguished from other specific eruptions elsewhere upon the cutaneous surfaces. Syphilides in the auditory canal are not frequent. Chronic aural diseases and uncleanness predispose towards their occurrence at this point. Papulo-ulcerative syphilides are accompanied by symptoms of otitis externa,—viz., a sero-purulent discharge, pain, and more or less swelling of neighboring parts. They tend to hypertrophy. Having become hypertrophied, they offer a marked tendency to abundant suppuration, efface the calibre of the canal more or less, and produce violent otalgia and various disturbances of hearing,—viz., tinnitus and deafness of all degrees. They resemble in appearance aural polypi. Such syphilides last, on an average, four or five weeks, and are healed without trace, by simple means,—viz., detersive washes, cauterizations with nitrate of silver, and dry local treatment. Excision does not hasten their cure.

3. Tertiary lesions in the auricle and in the auditory canal are in the form of gumma. Upon the auricle, on account of their development in a non-extensible tissue, syphilitic gummata produce at times singular deformities, which are dependent, however, upon their situation, their volume and number. In the auditory canal, gummy tumors, as observed so far, have been small, circumscribed, and unaccompanied by disturbed hearing. Finally, there are syphilitic exostoses of the auditory canal, following external otitis, generally two in number, one upon the posterior, the other upon the anterior, wall, narrowing the calibre of the canal about one-third (E. Ménière).

Middle Ear.—The guttural orifice of the Eustachian tube may be the seat of a chancre. The initial lesion at this point is accompanied by adenitis of the posterior cervical or of the submaxillary ganglia, and by secondary phenomena, generally intense,—viz., in the bucco-pharyngeal mucous membrane, painful angina, naso-pharyngeal catarrh, ozæna, and deafness. Upon the skin numerous syphilides occur. Syphilitic chancres of the throat can produce, by contiguity, obstruction of the Eustachian tube and hyperæmia of the tympanic cavity. The phenomena which are thus produced demonstrate the mode of action of secondary syphilitic anginas upon the middle ear.

Secondary syphilitic results in the middle ear comprise lesions arising from the contiguity of the parts to the pharyngeal lesions, and results entirely independent of contiguity. The first class, which are the most frequent, offer a train of symptoms varying according to the intensity of the lesions in the pharynx. When limited to the Eustachian tube they present symptoms of obstruction of this canal. Most frequently the cavity of the tympanum is invaded in its turn, with the characteristics of a simple acute otitis media, rarely passing to suppuration. The membrana tympani presents different changes, according to the intensity of the tympanic disorder. These results generally disappear with the cessation of the lesion which has given them origin. Nevertheless, obliteration of the Eustachian tube by cicatrices has been recorded by Gruber. Hence the prognosis relative to improvement of hearing in such cases should be guarded. General treatment must be aided by appropriate local treatment.

Direct syphilitic affections of the tympanic cavity consist in a chronic suppurative otitis media, in the production of which scrofula is held to play a predisposing part in some cases. Furthermore, Gruber and Schwartze admit the occurrence of an otitis media catarrhalis of the dry form, which affects the two ears successively, and is accompanied by changes in the membrana tympani and deafness, and which is not improved by general treatment.

In the tertiary stage disease of the middle ear is consecutive to gummy growths in the naso-pharyngeal region. Following the ulceration resulting from the breaking-down of a gumma, cicatricial obliteration of the mouth of the Eustachian tube has been observed.

Internal Ear and Auditory Nerve.—Syphilitic lesions in the internal ear occur in four ways:

1. Direct lesions.
2. Propagation of lesion from the middle ear.
3. Osseous lesions.
4. Central nervous manifestations reflected upon audition.

1. The affections of the internal ear by direct lesion manifest themselves sometimes in the secondary and sometimes in the tertiary stage. They often coexist with ocular affections. They are characterized by Ménière's symptoms: (1) Rapid diminution of the hearing supervening without noteworthy symptoms in either the external or internal ear, and which is unmodified by mechanical treatment. (2) Enfeeblement or even suppression of the perception of the tuning-fork and of the watch by the bones of the skull. (3) Amelioration and even cure of the deafness by a mixed and energetic treatment.

Clinical facts seem to be corroborated by anatomical research, which shows that the lesions in the labyrinth consist in a periostitis and in a hyperplastic cellular infiltration.

2. Labyrinth diseases by propagation of tympanic lesions present nothing special. There is an association of symptoms of otitis media and of otitis interna.

3. Osseous lesions which make an impression on audition are naso-cranial osteitis, caries of the mastoid apophysis, and especially caries of the petrous portion of the bone.

4. Cerebral syphilis is foreshadowed by various forms of aural or auditory troubles. Sometimes they are at first the only symptoms of the disease. They are generally accompanied by other cerebral symptoms. Sometimes they consist in subjective sensations limited to one ear, or they may be ambilateral. Sometimes they are manifested by a progressive diminution of hearing which may amount to absolute cophosis. They may, in fine, present all the phenomena of Ménière's disease. The prognosis is variable. Recognized from the outset, they are, fortunately, influenced by specific treatment. In some cases the deafness is permanent. Auditory maladies appear in the premonitory symptoms of specific tabes. Sometimes they are tinnitus in various forms, in other cases they manifest all the symptoms of Ménière's disease. They are of limited duration, and disappear more or less completely.

Hereditary Syphilis of the Ear.—Next to dental and ocular diseases, aural maladies constitute the most constant symptom of hereditary syphilis. They arise from contiguity of pharyngeal lesions and from direct lesion. As in acquired syphilis, so in the hereditary form, gummas and naso-pharyngeal ulcerations may communicate themselves to the middle ear and produce a simple otitis media,

which, aside from its mode of development, presents nothing special.

2. Primary manifestations by direct lesion are (*a*) otitis media suppurativa, and (*b*) profound deafness.

Otitis media suppurativa of hereditary syphilis manifests itself chiefly in early childhood. It becomes established without pain or any symptom of an acute process. The absence of pain, without being absolutely characteristic, is a diagnostic sign of some value. The course of the otorrhœa varies, sometimes being healed in a few weeks, and in other instances persisting for several years, and is accompanied by grave lesions of the tympanic cavity and of the membrana tympani, and ends in deafness.

Profound deafness in hereditary syphilis makes its appearance about the age of puberty. It occurs suddenly, without lesions in the middle or external ear, often being consecutive to a parenchymatous keratitis. Its onset may be characterized by vertigo and tinnitus aurium of various qualities. The deafness is on both sides. Sometimes both ears are affected at the same moment, at others successively. The lesion may be in the labyrinth, as shown by Moos, or it may be in the floor of the fourth ventricle in the ambilateral cases, as held by some.

The prognosis is grave. Specific treatment, which is efficient in parenchymatous keratitis, is ineffectual in heredito-syphilitic deafness.

This paper of Dr. Jégu gives a very good sketch of our present knowledge concerning the subject of syphilis of the ear. All otologists agree as to the rarity of syphilis in the external ear.

In a recent number of the *Archives of Otology* (vol. xiii. page 241, December, 1884), Dr. J. Zucker, of Berlin, gives an account of

TWO CASES OF CONDYLOMATA, AND ONE CASE OF PRIMARY SYPHILIS OF THE EXTERNAL EAR.

In this article Dr. Zucker states that Mracek (*Wiener Med. Presse*, No. 1, 1880), in his exhaustive report of over four hundred cases of the primary manifestation of syphilis outside of the genital tract, cites but three cases of primary syphilis of the external ear: one reported by Hulot (*Annales de Dermatologie et de Syphilographie*, 1878), of a child with a chancre on the mastoid process, attributed to infection by the nurse; a second of a chancre at the base of the tragus, of problematical origin; and, finally, a case from his own practice of a chancre on the lower portion of the mastoid, from the kiss of a prostitute. Pellizari (Milan, 1882) has recently examined with great care forty-one cases of the transmission of syphilis without coitus, and found only one in which the primary lesion appeared in the form of a chancroid on the left cheek, and a second one on the lobe of the auricle on the same side in the same individual. The origin of these primary infections, occurring in a father, was attributed to the use of a handkerchief which had been previously employed by his son to wipe his penis.

Finally, Dr. Zucker gives an account of primary syphilitic infection of the external ear, beginning near the tragus, and originating very probably from the kiss of a prostitute. Four weeks after the exposure an excoriation was noted near the tragus, which steadily increased in size and began to suppurate, and eight weeks after the exposure there appeared on the surface of each hand three or four small, round, slightly scaly efflorescences, which facilitated the diagnosis of primary syphilitic infection. Close examination of the ear, nine weeks after the exposure, showed that the anterior wall of the cartilaginous meatus bulged excessively inward and backward, that the tragus was livid red, twice as thick as normal, with its front surface covered by a darkly pigmented, radiating cicatrix. The entire parotid region seemed involved, was greatly swollen, hard as a board, but not at all painful. Beneath the angle of the inferior maxilla a bunch of separable yet indurated and enlarged lymphatic glands were found. The hearing was but slightly diminished, and there was no secretion from the ear. The posterior wall of the cartilaginous and osseous meatus, as well as the membrana tympani, were normal. The naso-pharynx was free from complications, and the genitals were intact.

AURAL SYMPTOMS OCCURRING IN HYSTERIA, AND THE HYSTERICAL ELEMENT IN AURAL DISEASE.

Drs. G. L. Walton and C. J. Blake have called attention to this subject in a recent number of the *Annales des Maladies de l' Oreille et du Larynx*, September, 1884. It is held by these observers that

aural symptoms occurring in hysteria, and, conversely, the hysterical element in aural disease, are subjects which should receive the attention of neurologists and aurists, but which have been somewhat neglected. It is important in some cases to recognize the fact that hysteria is a factor in aural disease, and also to carefully investigate aural symptoms when they occur in cases of hysteria and other nervous affections. "There are unquestionably numerous cases in which the subjective symptoms of an existing aural disease are increased to an extent which gives them undue importance in the mind of the practitioner by the co-existence of functional cerebral disturbance, evidencing itself in the train of symptoms to which collectively we give the name of hysteria."

Of the cases reported by Walton and Blake, the first illustrates the extent to which an aural disease, severe in its objective as well as its subjective symptoms, may be simulated by an hysterical patient; the second the influence which an existing aural disease of comparatively mild type may have in originating marked hysterical symptoms in a case already of hysterical tendency, and, reflexively, of exciting symptoms leading to the apprehension of graver aural disease.

A CASE OF GASTRIC ULCER—RECTAL ALIMENTATION—RECOVERY.

Read before the Philadelphia Clinical Society, December, 1884,

BY JAMES B. WALKER, M.D.,

Professor of the Practice of Medicine, Woman's Medical College; Lecturer on Clinical Medicine, Woman's Hospital.

JOSEPHINE C., aged 33 years, single, weight 98 pounds, presented herself at the Woman's Hospital Medical Clinic, January 13, 1881. She was a domestic, with a father living and well, and a mother dead of consumption. The patient had always been strong and well until the last three years, although the menstrual function, established at the age of 15, and which since then had continued regular and painless, had nevertheless always been extremely slight, never lasting more than a day or two.

Three years before, she had a severe attack of vomiting. The ejecta were very dark, and resembled "coffee-grounds." Once free blood was vomited. The stomach was at that time entirely non-retentive of food.

A year and a half after this attack she had a vomiting seizure, in which, however, no blood was vomited. In this attack she presented herself for treatment at the Woman's Hospital Dispensary, and was referred to my clinic. She was shown to the class as a case of ulcer of the stomach, and treated accordingly, and rapidly convalesced without admission to the hospital wards.

On November 25, 1880, another attack commenced with symptoms of dyspepsia, gradually increasing until intense pain was occasioned by ingesta, until all kinds of food, whether solid or liquid, were vomited. This aggravated condition has existed ever since.

During the long intervals between these three separate seizures the stomach has performed its work normally, no care being necessary in regulating the quality or quantity of the food in order for comfort.

On admission to the wards of the hospital she presented a decided cachexia, which, with her profound emaciation and exhaustion, raised a question as to the presence of malignant disease. The mucous membranes were all very pale, the tongue flabby, pale, glazed, and marked by the teeth along the border, with two stretches of a yellowish-white fur along the sides posteriorly, not reaching the edges or the tip. The stomach was *absolutely* non-retentive, even water in teaspoonful doses inducing vomiting. The bowels were greatly constipated, no movement having occurred for the two weeks previous to admission.

A tender spot has existed at the epigastrium since the commencement in November, and now a somewhat diffuse area of tenderness exists, which, however, does not involve the entire stomach.

The pulse is small, weak, and 88 per minute. Heart-sounds normal, except accentuation of second sound. Urine acid, specific gravity .1018, no albumen.

She was placed in bed, a blister applied to the epigastrium, 30 grains of bismuth subnitrate given every four hours; ¼ grain argenti nitratis at night; 4 ounces beef-tea by rectum every four hours, and a teaspoonful of milk by the mouth every hour. The bowels were at once moved by a copious enema. The first day in the hospital under this treatment the epigastric pain was intense. Vomited several times, but retained the rectal doses of beef-tea. The second day felt easier, but, as she still vomited after the small amount of milk by the mouth, gastric alimentation was suspended entirely. The blister raised but slightly, and was renewed in four days, when, although kept in place for twelve hours, it failed to vesicate.

The following day, third after admission, did not vomit at all, but rejected a small amount of each enema.

The ninth day, had an attack of pain in stomach, but no nausea or vomiting.

The tenth day, complained of rectal tenderness.

On January 29, fifteen days after admission, first complained of feeling hungry.

February 3, was given a teaspoonful each of milk and lime-water, which was repeated every hour, causing some pain, but neither nausea nor vomiting. It was discontinued after a few doses.

February 6, twenty-three days after admission, drank a small amount of milk without pain.

February 7, some beef-tea administered by the mouth, which acting kindly was continued; enemata continued also.

February 8, had pain after the milk, but none after the beef-tea; milk discontinued.

February 9, sat up an hour without much fatigue; nitrate of silver stopped; took three cups of beef-tea during the day.

February 10, took four cups of beef-tea without unpleasant results; enemata discontinued.

February 13, some milk with lime-water allowed, but it was digested with some discomfort; beef-tea caused none.

February 14, bismuth powders discontinued.

February 16, warm baths once daily, followed with olive oil inunctions on account of the harsh dryness of the skin.

February 17, thirty-four days after admission, small amount of solid food allowed once; no discomfort.

February 18, regular meals allowed without discomfort.

February 22, skin becoming moist and soft; felt no discomfort after eating; bowels moved naturally.

February 28, patient improving daily; lips becoming red; epigastric pain and tenderness no longer present.

March 4, forty-nine days after admission, discharged entirely well.

This patient presents several phases of peculiar interest.

1st. The cachexia was quite as marked as in most cases of gastric cancer, and much more so than in many cases of that affection which have fallen under my observation. But the disease was believed to be non-malignant, chiefly on account of the previous attacks which had each terminated in complete recovery, with comparatively long periods of health between them. Was it gastritis, and not ulcer? The rather more diffused tenderness than ordinarily exists in gastric ulcer left no doubt in my mind that there existed an aggravated and irritable condition of the mucous membrane about the area or areas of ulceration, but the still limited tenderness excluded to my mind chronic gastritis. Vomiting of blood had only occurred in the first seizure, three years before; but, as it is absent quite frequently in gastric ulcer, the want of it did not invalidate the diagnosis of the latter disease.

Again, the case is interesting on account of its recurrence. This, however, is the natural history of gastric ulcerations,—not that they must recur, but that they *may*. Certainly the cicatrix left after the first recovery will favor ulceration rather than the healthy mucous membrane in one not so affected.

The case is still further of interest on account of its persistent continuance. About November 25 the first symptoms were noticed. The time was fixed the more easily because this is one of our annually recurring *gastric epochs* from which time is reckoned. This persistence in a disease which naturally tends to recovery is, however, easily explained on considering the patient's habits.

Attempts at cicatrization were combated by the entire absence of any hygienic method to favor it until her admission to the hospital. Indeed, this, together with her great exhaustion, induced us to insist on her coming under the careful management of the hospital, for she was reported as entirely unable to supervise such method or submit to it except under strict discipline; whereas, under this, improvement commenced at once and continued uninterruptedly.

Etiologically, the case is not very instructive, except that the feeble attempt at menstruation suggests the possibility in a young woman of good health as possibly directly inducing the ulceration by the process of vicarious menstruation, with subsequent necrobiosis of the ecchymosed tissue, a condition apparently more frequently concerned in inducing this disease than all others combined.

The case is especially interesting, to my mind, in the long peried of time the patient was exclusively nourished by beef-tea digested and absorbed by the rectum. For twenty-three days the patient lived on these, and not only "held her own," but gained slightly in strength, if not in flesh. In these days of peptonized foods this would be sufficiently striking; but the fashion was not then instituted.

As regards the medicinal treatment, what was given answered the purpose, and under its administration improvement was gradual and persistent.

In cases of gastric ulceration with hemorrhage I am in the habit of using ol. terebinth., gtt. xx every two to four hours, in a little sweetened water.

My attention was first called to the hæmostatic action of this drug in the most nearly fatal case of gastric ulcer I have ever seen, which fell under my observation while still a student. Iron, opium, silver, lead, tannic acid, gallic acid, and some other agents were successively administered, with unvarying failure and simply aggravation of pain, discomfort, and hemorrhage, until the patient was almost exsanguine. Turpentine arrested for the first time the downward tendency, and under its use hemorrhage was at once arrested and recovery prompt and permanent. Since that time I have frequently used it in cases similar, though in none so severe, with invariable success, so that I look upon turpentine as the least irritating and, at the same time, most certain hæmostatic in hæmatemesis, especially when due to gastric ulcer. Its efficiency is too little appreciated by the profession. Nor is its province limited to the arrest of hemorrhage. Equally is it serviceable, apparently, in favoring the process of cicatrization, as advocated by the late Professor George B. Wood, in typhoid ulceration. It was not used in the case under consideration, as the irritable condition of the stomach demanded our utmost respect, and, knowing that the tendency of the disease was to cicatrization, only protective measures were instituted.

The question which arose at the outset of the case, as to whether it was one of malignant disease whose only tendency, despite whatever was done, was to destruction, or, on the other hand, an intensely aggravated case of a disease whose tendency is towards recovery if so permitted, was most satisfactorily decided in favor of the diagnosis of non-malignant disorder by the complete recovery of the case.

I am indebted for the official record of this case, upon which my paper is based, to Dr. Anna E. Broomall, then resident physician of the Woman's Hospital.

COCAINE DISKS.—The most convenient form for the employment of cocaine muriate for ophthalmic practice is in that of gelatin disks. Dr. Joseph Warren, of Boston, who suggests this method, has employed them with much satisfaction. Each disk contained about half a drop of an eight-per-cent. solution (gr. $\frac{1}{25}$). They were made for him by Metcalf & Co., and are recommended on account of their convenience and economy. —*Boston Med. and Surg. Journ.*, January 29.

A NEW METHOD OF STRAPPING THE TESTICLE.

BY WM. BARTON HOPKINS, M.D.,

Surgeon to the Episcopal Hospital and Out-Department of the Pennsylvania Hospital.

STRAPPING swelled testicle in the ordinary way, with adhesive plaster, is effective only so long as the yielding quality of the tissues of the organ is acted upon by the pressure with which the plaster is first applied, there being no elasticity in the muslin. The dressing must be frequently renewed, therefore, in order to follow up the rapidly-subsiding swelling. I have found that india-rubber prepared and applied in the following manner obviates this necessity, requiring renewal not more than once in four or five days, besides making much more persistent pressure than can be obtained by adhesive plaster. The advantages it possesses over the other forms of elastic pressure which have been employed, as the rubber bandage and the compressing-bag, are the perfect uniformity of pressure which can be exerted upon the entire organ, and the readiness with which it may be adapted to any case.

Two adhesive strips three-quarters of an inch in width are first made to encircle the scrotum at the upper portion of the testicle, in order to hold the latter well down in the bottom of the scrotal sac, as in the ordinary method, and to form an unyielding base of support for the elastic pressure to act upon. I originally used rubber for this, but found that the succeeding strips of rubber forced the organ partially through the encircling band thus formed, caused the material to become plicated, and thereby gave rise to pain. The testicle being thus fixed, four bands of rubber are applied after the manner shown in the accompanying illustration. These are made of "bandage-gum" cut into strips of the required length, an inch and a quarter wide, and retained with "rubber cement." A few drops of the cement are rapidly and thinly spread upon a strip with a spatula, and a few drops more upon the adhesive plaster and skin of the scrotum. These surfaces are allowed to nearly dry, care being taken that the rubber meanwhile does not curl up on itself and stick fast. One extremity of the strip is then placed upon the adhesive plaster posteriorly, carried forward beneath the testicle, and fixed in

front. Another is applied in like manner laterally, and two more obliquely, four

being usually sufficient to cover in the organ.

As with india-rubber used elsewhere for a permanent dressing to induce pressure, great caution must be exercised not to constrict the parts too firmly: about four ounces traction on each strip when the dressing is completed being sufficient to aggregate the maximum pressure likely to be required.

2018 Spruce Street, Philadelphia.

NOTES OF HOSPITAL PRACTICE.

HOSPITAL COLLEGE OF MEDICINE, LOUISVILLE, KENTUCKY.

CLINIC OF DUDLEY S. REYNOLDS, M.D.,

Professor of General Pathology and Diseases of the Eye, Ear, and Throat.

Reported by Allen Kelch, M.D.

GENTLEMEN, — Before introducing the patients who are to be the subjects of our study for the next hour, permit me to suggest that the best method of inquiry in most cases that attend a public clinic like this is to ignore all that rubbish commonly called "the clinical history of the case." Believe nothing of a material nature concerning the development of a disease or its progress which is not clearly marked in the phenomena present at the time, or which does not sustain some perceptible relation to the present phenomena. The application of this rule of caution shall be made apparent to you in the course of this clinic.

SYPHILITIC KERATITIS WITH ULCERATION OF THE LARYNX.

Mrs. G., æt. 39, came here three months ago with keratitis punctata, and incrustation along the margins of the lid matting the lashes together and causing the lids to adhere during the night. She had a papillary eruption about the face, chiefly upon the forehead, the nose, the cheeks, and the chin, with a few papules about the neck, and fewer still upon the wrists and arms; the eyes were morbidly sensitive to light; the lids were swollen, and the hot tears flowed freely upon the slightest exposure to light. She claimed to have neuralgia, and mentioned the name of a respectable practitioner here in the city as having attended her for several weeks consecutively for that disease. She says he gave her quinine and morphine for a while, and subsequently arsenic. He blistered her behind the ears. She said she had never been sick a day before in her life, except in confinement. She claimed to be the mother of five healthy living children, the youngest of whom is now eight months old. She says her husband's health is excellent.

On her first appearance here, a muffled and peculiar tone of voice was noticed whilst she related this history I have just repeated. She said the breaking-out she had was heat and mosquito-bites. As some of you may remember, I had her statements recorded for the very purpose stated in the beginning of my lecture to-day.

Examination of her throat at that time revealed extensive phagædenic ulceration, beginning at the base of the epiglottis and extending down in front of the anterior attachment of the left vocal cord.

She was ordered a half-ounce of bicarbonate of soda to be dissolved in six ounces of water as a lotion for the eyes, for the purpose simply of dissolving and clearing away the accumulated matter in the lashes; an ointment composed of one scruple of boric acid and a half-ounce of petrolatum was directed to be applied to the lids morning and night. She was directed to take of iodide of potassium one ounce, two ounces each of camphor-water

and simple syrup, a teaspoonful in a glassful of water every four hours.

She made rapid improvement; in a week the ulceration of the larynx had almost entirely healed; the eyes were now less sensitive to light; the lids were no longer swollen, and their margins were clean. The strength of the medicine was then increased by the addition of ten grains of the iodide to each dose. In a week more her voice was quite natural; she had improved in flesh, and she said she had suffered no pain at all after the first dose, and she was able to come to the clinic alone. There are now no appearances of disease beyond a few very minute and dimly-marked opaque spots in the cornea.

I sent for this woman to come to-day that we might institute this comparison between the facts in the course of her disease and the history she gave. It is clearly apparent to my mind, both from the nature of the corneal disease and the ulceration of the larynx, laying aside the equally almost certain evidence afforded by the eruption upon the face, that this woman was suffering from constitutional syphilis. The result of the treatment has fully confirmed the diagnosis. Now, as to the peculiar characteristic appearances in the cornea and in the larynx. First, any distinctly and clearly marked effusion of plastic matter into the proper substance of the cornea, involving both eyes and occupying different circumscribed positions in the cornea, is almost certainly syphilitic. It is as clearly characteristic as the sore with everted margins and gray base commonly called the hard chancre, the true chancre, or the Hunterian chancre. Likewise the ulceration in the larynx, sharply defined with ragged and everted margins, surrounded by inflammatory effusion, presents all the characteristic appearances of syphilitic ulceration. This papular eruption upon the skin is not so positively indicative of syphilis. It is likely a practitioner inexperienced in dermatology might confound it with some other form of papular disease.

The history given by Mrs. G. might have been, according to her judgment, entirely truthful. She is not a woman, as you observed when she was present, of sufficient intelligence to be able to give such a well-marked history of periodical neuralgia and to paint so good a picture of what is in this section of country called chronic malaria.

If this were an uncommon sort of case I would not devote so much time perhaps to pointing out the discrepancies between the phenomena present and the so-called clinical history, but it too often happens that the general practitioner of medicine does not exhibit sufficient curiosity to induce him to look into the larynx and nasal passages, or to concentrate the light with an ordinary converging lens in such a manner as to illuminate the cornea. Some very excellent practitioners—men well informed in the literature of the profession—exhibit this carelessness, which is, in cases like Mrs. G., little less than criminal.

As she enjoys good vision (sufficient for all her requirements) and suffers now with no pain or other evidences of disease, she may go, with the injunction to take forty grains of iodide of potassium in a tumblerful of water every night for the next two months.

OTITIS MEDIA PURULENTA

J. H., 18 years of age, an intelligent young man, a tobacco-stripper. For several years he has had a progressive impairment of hearing. Two weeks ago to-day it was extremely difficult, as you may remember, for me to make him hear my voice; the external auditory canals were both filled with muco-pus containing a quantity of dirt from the tobacco-factory. This was mopped out with small portions of cotton-wool rolled upon the end of a probe; the Eustachian catheter was then employed, and air blown through the middle ear, bringing away a considerable quantity of muco-pus. A solution of chloride of sodium (3–3) was then employed, about one minim being placed in the distal end of the catheter, and, the nozzle of the Politzer air-bag being placed over the tip, forcible compression was made, driving the minim of solution through the walls of the catheter in such a way as to permit the escape of it in the form of spray into the Eustachian tube, and by continued blowing the dissolved inflammatory matters were easily blown out through the perforated drum-membrane. Following this a single drop of Lambert's listerine was blown through the catheter in the manner just described. This practice has been kept up once a day since, through

the kind attention of my assistant. Now Mr. H. is able to hear my watch at two inches from the right ear and three inches from the left. He experiences no difficulty in hearing all conversational tones.

Another difficulty from which he suffered, and which created considerable amusement here at our last clinic, deserves attention now. You have doubtless noted the absence of the very offensive odor which attended his presence in the arena at his last call here. You may remember he told us the source of the odor was his feet, and that a member of the class, and two or three outside practitioners, had for weeks been taxing their skill in the use of various kinds of lotions to overcome it. I dare say you will recall to mind the advice I gave him on that occasion,—to go home and buy a flesh-brush and a bar of good soap, and to take a bath every morning before breakfast and put on a clean pair of socks daily.

[Amidst great laughter the young man announced that the soap and water had done more good than all the medicines, and if he had only known that before he could have saved a good deal of money which he had spent at the drug-store.—REP.]

The affliction called stinking feet is singularly limited to people of constipated habit and whose feet are strangers to soap and water and clean socks.

ANTERIOR SYNECHIA FOLLOWING PERFORATION—USE OF COCAINE.

Annie F. was brought here by a member of the class a month ago with the left eye closed: she was anæmic and emaciated. She had just recovered from the measles, and the gentleman who brought her to the clinic said that the measles had "settled in her eye." Examination showed a perforating ulcer of the cornea about midway between the inner and the inferior margin of the cornea. The iris was at that time bulging through the opening, and the child was in great pain. A solution of the sulphate of eserine, one grain to the ounce of water, was directed to be instilled three times a day, and the eye to be closed with dry absorbent cotton secured in position by a strip of adhesive plaster extending from the cheek to the forehead. The other eye was directed to be protected from the glaring light by what are called in London "smoked eye-protectors." The smoked eye-protector is known in this country as the "London smoked coquille," or shell-shaped glasses.

She was ordered ten minims of the syrup of the iodide of iron after each meal, and, with some dietary regulations, made rapid improvement. The ulcer soon healed by granulation and cicatrization, the iris, however, remaining attached. It is desired to have her return to school, but on the slightest attempt to read the eyes fill with tears. This reflex irritation of the eyes, shown by a sense of discomfort and a sudden flow of tears on attempting to read, is no doubt chiefly due to the fact that the pupil of the left eye has been almost entirely obliterated, by the falling of the iris into the lips of the corneal opening at the time of the perforation of the cornea by the ulcer. When no particular strain or effort is required to see near objects, no irritation is developed; as soon, however, as the patient is able to see a little with the left eye, the accommodative effort to harmonize and at the same time to fix the two eyes upon an object calls forth the phenomena described. I have here a small iris-knife strikingly similar to that of Dr. Hays, but curved upon the flat. Passing this knife through the cornea, and taking great care not to permit the aqueous humor to escape, I am able, as you see, to carry it across the anterior chamber above the pupillary opening and obliquely downward toward the nasal side. I am now able to get the point of my knife below the point of attachment of the iris to the cornea, and by this very delicate and carefully conducted sawing motion you observe now that the iris is cut loose and has fallen away from its position in contact with it, and the pupil at the same time is much enlarged. No hemorrhage has occurred, which I attribute in part to the hæmostatic powers of the cocaine (a solution of which was instilled five minutes before the operation was begun). The patient remains unconscious of the nature of the proceeding, and it evidently produces no pain. On the withdrawal of the knife a slight oozing of aqueous takes place. It is difficult to account for this, and it has been remarked by other operators, some of whom have not hesitated to attribute it to the effects of the cocaine upon the connective-tissue fibre of the cornea, which causes the opening a moment ago occupied by the knife to close speedily upon its with-

drawal. I myself believe that, while the cocaine may have this effect, in this instance it operates in another manner not before mentioned,—viz., it reduces the tension of the eyeball. This effect of the drug opens up a new field for its application in the treatment of the painful tension so often present in phlyctenular keratitis, and greatly diminishes the danger of iridectomy for the relief of glaucoma, as I shall now show you.

GLAUCOMA—IRIDECTOMY UNDER COCAINE.

Mr. A., 52 years of age, is now blind in the right eye, the pupil of which is widely dilated, the eyeball tense and painful to the touch. This obeys the law of periodicity in this: that two months ago it became painful and tense, the patient had flashes of light, with an unnatural halo around artificial flames of light, and on going into the street he was astonished at seeing only part of an object at a time. The pain continued for forty-eight hours, and then subsided, leaving the eye somewhat tender to the touch and with impaired vision, the halo remaining around the gas-jet or the lamp-flame. In about ten days the same phenomena returned, accompanied by a violent sick headache lasting about forty-eight hours and leaving the patient in a state of great nervous prostration. At intervals regularly of about ten days these phenomena recurred, until two weeks ago sight was extinguished in the right eye. Four days ago the phenomena reappeared in both eyes, creating so much alarm in the mind of the patient that he at once left his home and came to this city to find relief.

I saw him for the first time this morning. He was then suffering morbid sensibility to light and some nervous headache. He had tension +2 in the right eye, and tension +1 in the left. I instilled into each eye one drop of a solution of hydrochlorate of cocaine (gr. ij–ʒj.) In five minutes he opened his eyes and faced the window without discomfort. In seven minutes the tension of each eye was perceptibly reduced. In eight minutes I made an ophthalmoscopic examination, discovering what has long been recognized as one of the objective signs of glaucoma, the sharply-cupped disk in the left eye, the beaded appearance of the retinal veins in the right, the disk being deeply cupped in both. This cupping of the disk is, in fact, a well-marked depression of the optic nerve.

Strangely enough, the examination provoked no reflex irritation; in fact, it gave the patient no pain whatever.

I shall now proceed to instil one drop of the cocaine solution into each eye, to prepare him for the removal of a portion of the iris.

[Reporter's Note.—3.40 P.M., instillation made. 3.45, patient declared insensibility of the eye and mounted the operating-table. 3.47, speculum introduced between the lids of the right eye, and the operator introduced Jaeger's keratome just within the margin of the sclera, passing it on into the anterior chamber, withdrawing it cautiously, allowing the aqueous humor to flow out slowly. The iris appearing between the lips of the wound was seized with toothed forceps, drawn out, and the protruding portion snipped off with scissors. This was followed by no hemorrhage, and after rubbing the angles of the wound with the index-finger to prevent the incarceration of portions of the iris, a drop of a solution of eserine (one grain to the ounce of water) was instilled, and the speculum withdrawn. 3.52, the patient's left eye, being still anæsthetic, was subjected to a precisely similar proceeding. 3.55, iridectomy had been completed in both eyes without any pain whatever and without hemorrhage.]

Gentlemen, you observe how quietly this man submits to the operation of cutting into the eyeball, drawing out and snipping off with the scissors a portion of the iris, and, what may appear to be the ordinary occurrence to an inexperienced observer, no hemorrhage followed. I can scarcely remember the time when I have done iridectomy for the relief of glaucoma without some hemorrhage. Indeed, it is one of the great sources of danger in the operation, but, as you have now observed, this operation was entirely painless as well as free from hemorrhage; no nausea, retching, or vomiting, no sudden flow of blood to the head and face, and consequently the vessels subjected to no unusual tension, which removes all the sources of danger to the eye from the operation. These disagreeable phenomena almost uniformly attend the operation under chloroform or ether, and the proceeding is so painful upon the morbidly sensitive eyes

of the glaucomatous subject that it is generally practised with their aid. The cocaine is unquestionably the greatest discovery of modern times, far exceeding chloroform in its applications to ophthalmic and aural surgery. It may be well to note that the hydrochlorate of cocaine made in this country by McKesson & Robbins, of New York, is that which I am now using. It is in every respect equal to that made by Merck, of Darmstadt.

IMPACTED ACCUMULATIONS OF LONG STANDING IN BOTH EARS.

Mr. S., 49 years of age, suffers impairment of hearing which he thinks is hereditary. He is desirous, however, of having something done to arrest, if possible, the further progress of the disease. He hears my watch upon pressure against the tragus; he hears it equally well when it is brought into contact with the mastoid process. On lying down at night he has for years been disturbed by hissing sounds. He has never done anything by way of treatment, because his father and his mother were both hard of hearing, he has several brothers afflicted in the same way, and he feels confident the disease is hereditary.

Examination shows an accumulation of something almost exactly the color of the membrane lining the auditory canal, which is entirely filled. With a blunt hook about the size of a No. 2 Bowman's lachrymal probe it is easy to detach the margin of the foreign substance occupying the external ear. By careful coaxing with this blunt hook the whole mass is moved from its position, when the patient is instantly seized with a tickling in the throat and cannot restrain the disposition to cough. Coaxing, as you see, still further now brings this enormous mass, which is something more than a quarter of an inch in diameter, somewhat cylindrical in form, and just about three-fourths of an inch long. As you observe, it is covered with a whitish film, which is evidently a cast from the lining of the external auditory canal, including the outer surface of the drum-membrane. Inspection now shows that the walls of the external auditory canal in contact with this foreign mass are quite thin, suffused with blood, and look ready to bleed. Mopping the passage with a solution of carbolic acid (ʒss to the ʒ of distilled water) by means of a piece of cotton rolled on a probe and dipped in the solution causes a slight sense of pain and smarting, which is, however, but momentary in duration. Holding the nose, the patient is now able by forcibly blowing to distend the cavity of the tympanum and cause the drum-membrane, which was before depressed, to assume its normal position, when the patient exclaims that he "feels an awakening into a new world." He is at once able to hear the watch at ten inches which but a few moments ago required to be pressed against the ear.

Inspection shows the other ear to be in precisely the same condition. The same process of manipulation as that employed in the other ear brings forth a similar mass of foreign matter. This seems to be compounded of an outer tough, amber-colored substance, like that which constitutes the crust upon the surface of an eczema, the whole enclosed by a film of epidermis. There is no telling how long this formation has been in the ear. The patient does not remember when his hearing was as acute as it is now since the removal of this foreign matter. He is ordered to have one grain of resublimated iodine, five minims of pure carbolic acid, and half an ounce each of glycerin and distilled water, with enough iodide of potassium to make a good solution, to be dropped into the ear every morning and evening,—the carbolic acid to allay irritation, and the iodine to stimulate the circulation and glandular functions of the membrane. The method of inflating the middle ear by holding the nose, closing the mouth, and forcibly blowing is known as Valsalva's method, although every boy in the world who ever went swimming has practised it to expel the water from his ears.

This patient may go with the assurance that such accumulations in the ear are in no way hereditary; and should any further trouble appear, we hope to be able to afford as prompt relief again as we have done to-day.

TRANSLATIONS.

PRIMARY SCLEROSIS OF THE COLUMNS OF GOLL.—In *Le Progrès Médical* (No. 49) an interesting case of typical progressive sclerosis of the spinal cord, occurring in a man, 48 years of age, is reported by M. L. Camuset. With enfeeblement (ideas of

grandeur) of the mental faculties, he had some paresis of the lower extremities, supposed originally to have been produced by cold. His pupils contracted and expanded normally; his sight was good. Walking was difficult and slow, but he had no lancinating pains and no gastric crises. The difficulty in standing upright was not increased upon shutting his eyes. The patient's malady remained stationary for a year, and then without known cause he became very much excited, and finally developed acute mania ten days before death.

At the autopsy the spinal cord appeared healthy to the eye, but under the microscope a manifest sclerosis was localized at the innermost part of the posterior pyramids. In the cervical region, where the column of Goll is very limited, it was seen that the sclerosis had invaded the entire column in its transverse section. This was also noticed in the dorsal and lumbar regions, though in the latter the lesion was much less regularly distributed. The lesion was more marked posteriorly, and progressively diminished towards the front. The brain appeared normal; there were some evidences of chronic meningitis, but none of the lesions of general paralysis.

The following reflections were offered upon this case by the author. He passed without discussion the interesting question of the association of medullary sclerosis with mental alienation, which was made more interesting by the absence of the usual cerebral lesions of general paralysis. He regretted that the sensory and motor phenomena had not been studied more minutely during life. However, observation showed that a sclerotic phlegmasia produced by, or at least immediately following, a chill had been localized in the columns of Goll, and showed a tendency to extend, so that the root faisceaux would certainly have been attacked in their turn. In this case the patient, had he lived longer, would have shown the symptoms of ordinary locomotor ataxia, which symptoms were wanting because they did not have the time to develop. The columns of Goll are made up by the commissural fibres, and their lesion does not produce visual troubles, ataxy in walking, or fulgurant pains. It was found, moreover, that the patient could stand with his eyes shut without being any more unstable than when his eyes were open.

Acid Remedies and their Relation to Dyspepsia.—Professor Riegel, in the *Archiv für Klinische Medicin*, December, 1884, contributes a very long article on the Pathology and Diagnosis of Diseases of the Stomach. He concludes that a small mixture of organic acid produces no injurious influence upon digestion, but that a greater quantity of this organic acid, as well as muriatic acid, will in a high degree impair digestion. On this account the disadvantageous influences of sour fermentation in many forms of dyspepsia may be attributed to the presence of too rich a mixture of acid, especially lactic and butyric acids. The favorable operation of an alkaline remedy in a case of the abnormal formation of acid can therefore be readily accounted for. On the other hand, his experiments demonstrate that the exhibition of muriatic acid, which has become so popular of late in the various forms of dyspepsia, is not justifiable or even safe. Too much acid in the treatment of diseases of the stomach is as undesirable as too little. Muriatic acid can be useful only in those cases where a lack of the required quantity of acid is evident. P.

On the Action of Ergot.—Dr. R. Kobert, in the *Archiv für Experimentelle Pathologie und Pharmacologie*, December, 1884, contributes a paper on the Action of Ergot. He concludes that the freshly-prepared ergot will undoubtedly produce strong contraction of the uterine muscles. This is a well-established fact, one which the Chinese possessed a knowledge of a thousand years ago. Ergot is capable of producing contractions of the uterus sufficient to cause delivery and produce abortion, and is also capable of inducing contractions sufficient to control hemorrhage from that organ.

He has received positive proof of the poisoning in animals. Cows which eat the ergot while in pasture frequently abort. He considers it almost useless to administer ergotin by the mouth, as it cannot, after reaching the stomach, induce any uterine contractions, because it becomes too much dissolved and weakened. He also claims that, while the subcutaneous injection of ergotin may sometimes induce uterine contraction, few preparations are to be considered reliable. Ergotin, he thinks, is active only when it contains cornutin. P.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, FEBRUARY 7, 1885.

EDITORIAL.

TREPHINING THE SKULL FOR A GROWTH IN THE BRAIN.

IN our London letter is the fullest account that we have yet seen of the case of Dr. Hughes Bennett, in which, after a diagnosis of a localized lesion in the cerebral convolutions, Mr. Godlee trephined and removed a neoplasm. Strangely enough, as it appears to us, this case was immediately published in the *London Times* as a triumph of vivisection, the sole credit being awarded to Ferrier's experiments for the successful operation. A glowing picture was given of the salvation from certain death of the patient, and a contrast drawn between the restoration to health and usefulness of the bread-winner of the family and the value of sundry monkeys and dogs which had been sacrificed in order that the profession might gain the necessary knowledge to treat the case. Unfortunately for this argument, as it happened, the patient perished with meningitis, and most distinctly was not cured by the operation. In an editorial "On the Justification of Vivisection" in the *British Medical Journal* this case is discussed at length, but the impression given by the description is that the diagnosis and operation were solely directed by the interpretation of the symptoms furnished by physiological experiment. "Guided by these symptoms," are the words, "a tumor was diagnosed in the cortex, in the upper part of the fissure of Rolando."

The account given by our highly esteemed London correspondent, however, throws more light upon the case, and communicates features which had not previously been published, so far as we are aware. There was a history of a blow upon the right side of the head (it will be remembered that this is the common history of glioma), followed by excruciating pain over the vertex, with a spot of localized tenderness on deep pressure in the upper parietal region a little to the right of the middle line, the symptoms of twitching of the muscles of the left side of the face, and convulsive seizures in the left arm and leg, followed by monoplegia of the arm and paresis of the leg, with attacks of vomiting cerebral in character. Upon such a basis modern surgery could make, and undoubtedly did make, the diagnosis of a small tumor involving the cortex in the position indicated, with sufficient certainty to warrant the operation. Thus far the credit might certainly be divided between clinical surgery and Hughlings Jackson, to whom we owe much of our knowledge of localized discharging lesions in the brain. Take away the history of the case, the localized tenderness and pain, the Jacksonian epilepsy, and leave only the symptoms of monoplegia and paresis, and it would be a bold surgeon who should operate in a case with nothing more to guide him than the information afforded by the study of motor centres in the brain made by Hitzig and Ferrier, especially if he were at all familiar with the writings of Brown-Séquard upon the same subject.

This is not written to decry the value of vivisection (it cannot be denied that cerebral localization aided in the diagnosis), but to discourage what appears to be a tendency to exaggerate the value of physiological experimentation at the expense of clinical medicine and surgery. Vivisection owes its justification to its ability to contribute to knowledge, and not to the result of attempts to utilize that knowledge in medical practice, attempts which may be premature and injudicious. Dr. Klein was certainly right in taking the

position before the Royal Commission that vivisection is to be practised with a view of adding to our stock of knowledge, and not with any idea of its immediate practical application to medicine. In this view those engaged in original investigations generally concur.

THE INSANE DEPARTMENT OF THE PHILADELPHIA HOSPITAL.

SOME of the members of the consulting medical staff of the Philadelphia Hospital have presented a communication to the Board of Guardians pointing out many glaring defects in administration, in the Insane Department especially, arising, it is distinctly stated, through no fault of the chief medical officer, Dr. Richardson, who is doing the best that he can under adverse circumstances, hampered as he is by official parsimony and Bumble-ism. The present buildings are obviously unfit for hospital purposes; they are ill ventilated, and are so shamefully overcrowded and under-attended that poor insane patients cannot under present circumstances receive either proper medical attention or have their physical necessities decently provided for. The Insane Department should be removed to a distance from the city, out into the open country, where appropriate buildings should be provided, and where the insane might be classified and receive all the advantages of skilful and considerate treatment. Humanity and justice demand that the wards of the commonwealth shall be kindly cared for.

We hope that the matter will not be allowed to rest until the city authorities rise to the appreciation of the necessity of providing accommodations more in keeping with the high standing of the community. In the mean time, should a fire occur at Blockley, the Kankakee horror might be re-enacted at our very door. The move has not been taken in this matter any too soon.

INTERNAL URTICARIA.

A VERY interesting communication was made during the last month to the Clinical Society of London by Dr. J. J. Pringle, on a case of recurrent hæmatemesis associated with and possibly due to urticaria. The patient had had a series of attacks of urticaria due to errors in diet apparently. Finally, after several years, the spells occurred with increasing frequency and severity; the tongue, mouth, and fauces now showed symptoms of disorder, and there was vomiting of a clear, watery fluid. During the succeeding year urticaria was almost constant, and at intervals attacks of great severity occurred, during which large quantities of pure red blood were vomited. There were no purpuric wheals or spots detected. Associated with this condition was a hypertrophy of the heart. The hemorrhage was thought to be due to capillary rupture. He subsequently had attacks of gout.

In discussing the paper, Sir Andrew Clark said that he had upon a former occasion pointed out the association of asthma with urticaria, regarding the former as an urticarial affection rather than a spasmodic one. On the other hand, systematic writers on dermatology consider asthma as one of the causes of urticaria.

ÆSTHETIC ORCHIDECTOMY.

AN editorial in a contemporary upon the Semiramidian operation states that "the testicles have been removed in order to secure sopranos for the Church," but does not state from what the innocent sopranos are to be made secure. Can it be possible that they are in greater danger of molestation or feel a greater sense of insecurity among those of the male sex whose register embraces the upper notes of the scale than from those who by nature are less aspiring in their vocal efforts? Is the tenor more base than has been suspected, and the bass less so? We pause for a reply—from the sopranos.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

WHEN Professor Ferrier went down to the West Riding Asylum, near Wakefield, at Easter, 1874, the writer accompanied him, and was a witness and a voucher for the earliest of those experiments on the brain which have since made Ferrier's name world-famous. After seeing a good deal of his work, the writer expressed himself to the effect that before ten years were gone and past some surgeon would remove a tumor of the brain under the direction of some physician. The diagnosis would be so precise that the surgeon could be told the exact spot for his trephine. That forecast has been verified. Dr. A. Hughes Bennett (son of the famous John Hughes Bennett, Professor of the Institutes of Medicine in the University of Edinburgh) recently diagnosticated the position of a tumor in a man's brain, and under his instructions Mr. Rickman Godlee, Assistant Surgeon to University College Hospital,—a man of rare promise,—cut through the skull and removed the tumor, with immediate relief to the symptoms. The case got into the journals, and thereupon a storm began to blow. Such a proceeding was so direct an outcome of knowledge founded upon experiments on animals—not only the diagnosis, but the line of after-treatment even which rendered such an operation defensible—that, of course, the anti-vivisectors must be stirred up. These cantankerous mortals having taken up the position that nothing had been learned from experimentation upon animals, that nothing worth the having had come out of the cruelty to animals, and had been so blatant about their opinions,—now an opportunity having come for taunting them, it must be made the most of. Putting up a red rag to a bull excites that animal; and a letter in the *Times* giving an account of the case and the operation roused them into action like a swarm of hornets. Letter followed letter until the public must pretty well comprehend the merits of the case by this time. Unfortunately, as it happened, the man died of an after-consequence of his surgical wound (meningitis), and so the anti-vivisectionists have a leg left to stand upon. Still, the operation was a success and a path-breaking experiment which must lead to a new departure in the treatment of encephalic disease. Not unlikely the trephine and the aspirator will come into play ere long in serous effusions, and even in apoplexy when blood is being poured out and compressing the contents of the skull.

One outcome of all this contention is to bring Professor Ferrier and his work prominently before the public, doubtless to his professional advantage. Unfortunately, however, the professor happens to be a man cast in a sensitive mould, and the attentions of his enemies are very unpalatable to him. Most men would thank their stars for such an opportunity of coming before the public, and look upon the assaults of these enemies as blessings in disguise; but not so in this case. It was no doubt highly unpleasant to read at breakfast that three barristers have applied for a warrant for you at Bow Street, as Professor Ferrier did some time ago when the anti-vivisection party thought they had caught him at a disadvantage; but there is a silver lining to the cloud, or a golden lining, rather, perhaps!

Another outcome is, of course, the spread of a knowledge of the nervous system and its diseases, now so rapidly advancing with mighty strides. Perhaps some account of the case may be welcome to your readers. The patient was a healthy young man who, four years ago, was hit on the head by a piece of timber, but not so severely as to lay him up. Occasional headaches came on after this, and then occasional twitchings of the tongue and left side of the face. Then the "fit" ran from thence down the left arm and leg, without loss of consciousness. At intervals he had more complete convulsive seizures. Twitchings of the face and arm occurred daily, but never together. Loss of power in the left arm followed, and, later still, weakness in the left leg. The general health was good, but pain over the vertex was frequent and violent,—that excruciating pain which Dr. Moxon (in his articles on headache which appeared in the *Lancet* a few years ago) has described as occurring with organic disease of the brain. Tenderness on deep pressure was found in the upper parietal region, a little to the right of the middle line. Cerebral vomiting was also present. The congeries of symptoms told of cerebral mischief, probably a tumor. Further indications pointed to its locality,—viz., the right side of the head and near the motor centres in the neighborhood of the upper third of the fissures of Rolando.

Dr. Bennett argued that it must be of limited size, as the hand-centres were alone severely injured, irritation only being exhibited in the leg, face, and eyelid. It was a careful diagnosis, which every unprejudiced mind will admit could not have been made, or even approached, without the knowledge derived from the early experiments of Fritsch and Hitzig, and the more complete and elaborate work of Ferrier. The only aid that could be given to the patient was the removal of the growth, which was clearly near the cortex. Mr. Godlee removed a triangular piece of the skull, slit up the dura mater, and exposed the surface of the brain. Nothing abnormal was to be seen. Still, so confident were all in the accuracy of the diagnosis that an incision was made into the brain, when a hard glioma was felt, which was about the size of a walnut. It was removed without

difficulty. The hemorrhage was arrested by the galvano-cautery, and the edges of the scalp brought together by sutures. The result was magical. The vomiting ceased, the lancinating pains in the head vanished, the convulsions disappeared, and the patient felt well and expressed the greatest gratitude for the relief so afforded to him. For twenty days this went on, the only cause for anxiety lying in the wound, which was not satisfactory. Then, unfortunately, symptoms of acute meningitis set in, to which the patient ultimately succumbed. The progress of the case, however, was such as to demonstrate the effects of the removal of a tumor of the brain as regards relief to the symptoms it set up. The untoward result was one of the accidents which attach to the serious operation of trephining, and had no special reference to the malady for which the operation was performed.

The scene of this operation will some day be put on canvas, and the operation itself will become historical. The practical outcome of vivisection was completely satisfactory as illustrating what we owe to careful experimentation. And if Professor Ferrier's experiments still need any justification, that is now forthcoming. The experiments performed by Professor Gerald Yeo teach us that, with antiseptic precautions, injuries to the brain can be inflicted with practical impunity. It is impossible to criticise the surgical after-treatment of the case until it has been laid before the profession in its entirety; but it is not absolutely out of the question that there may yet be some details in skull-wounds, which further familiarity therewith may teach us, entailing dangers that are avoidable. It is a great pity, under the circumstances, that the man died; but he lived long enough to establish the value of the operation.

Beyond its direct value to the profession, this case is a triumphant vindication of the value of careful experimentation upon the lower animals, and of the accuracy of those observations which have made Ferrier so well known. Without these for a map of the brain, it would be impossible to interpret the complex symptoms furnished by clinical observations. Without them, indeed, these last, however carefully collected and laboriously sifted and arranged, would have remained a mass of fragments which no genius probably could ever have cast into form. But by the light thrown on the brain and the functions of each part of it by experiments performed upon the brains of animals (which are clearly built upon the same plan as that of man) it is now possible to construct a correct diagnosis of what is going on in the brain beneath the bony skull. If Dr. Bennett could have made the coverings of the brain transparent,—nay, more, could he have peered into and seen through the cortical substance of the brain itself,—he could not have ascertained more than he did, or been more accurate in his diagnosis than he actually was. Twenty years ago such a diagnosis was out of the question,—indeed, no one would have attempted it; and now no one is taken by surprise, and all take the case in a matter-of-fact way. We are already so familiar with the localization of function in the brain that, instead of any surprise, indeed, we receive the announcement of the novel procedure as something that we have been looking for, with the gratification, however, of having our anticipations realized for us and our faith corroborated. Fritsch and Hitzig, and still more my countryman, Ferrier, have not only mapped out the brain, but they have done much for suffering humanity.

The other matter which is exciting attention in the medical world here at the present time is that of a teaching university for London. Strange as it may appear, London has, until very recent times, had no university at all, and the one it possesses at present is merely an examining board. The information required has to be sought and gained somehow and somewhere; not promiscuously, however, but from certain recognized teachers. A man presenting himself for the M.B. of London has to furnish certificates of having attended sundry lecturers whose lectures are "recognized by the University of London." Logically it ought to be seen if he possesses the requisite knowledge when put to the test, but he ought to be allowed to acquire it as, where, and how he pleases, provided he has got it. Where the man who seeks his B.A. London has to get his lore is unknown to me, but he has to acquire a fair lot somewhere. From time to time attempts have been made to start a regular university in London, but so far the attempts have signally failed. It is very desirable, from the medical aspect of the subject, that such an institution should exist; at least so I think, as an old Edinburgh University man. Before a man can be chosen a Professor, he must at least have manifested some familiarity with the subject of which he has to treat; possibly, too, he may be required to have shown some capacity to impart knowledge, but this is quite a secondary affair. It is a well-recognized fact that some men cannot teach, while others can. The present Professor of the Institutes of Medicine in the University of Edinburgh is an instance of innate teaching-powers, and so also was his predecessor. On the other hand, the late Professor William Pulteney Allison, learned and wise as he was, had no knack of imparting knowledge, and even his work on "Pathology and Practice of Physic" is utterly unreadable by any one who is not perfectly familiar with the subject. But he fulfilled the first requisite in any degree,—viz., the possession of knowledge. The late John Goodsir, the famous anatomist, was as good an expounder and teacher as he was profoundly

versed in his subject. The professors of the University of Edinburgh were not only chosen men, but they gave complete courses of lectures. If a man attended the class regularly and took notes, he could pass in that subject without other reading, as many practically did. The student had no occasion for private tuition: he could have it if he pleased.

One matter was also recognized,—viz., that a student may learn from one man, but not from another. On this principle the University of Vienna has two professors on each subject, giving the student a choice. In Edinburgh this difficulty was met by allowing certain extra-mural lecturers whose lectures were recognized. But before each man got this recognition he had to do something to convince others of his fitness.

In London, unfortunately, things are very different. There are eleven teaching hospitals in London, each with a full staff of lecturers. Now, large as London undoubtedly is, it is possible to question whether the medical profession here could furnish eleven competent professors on each medical subject. Say medical jurisprudence, for instance. Are there eleven men competent to teach the subject fully? It is very doubtful. Yet there are at least eleven men who deliver lectures on the subject. I have had the curiosity to see of whom these eleven consist, and the less said on the subject the better as regards the list. Two, or perhaps three, have exhibited some special acquaintance with the subject, and two competent Professors of Medical Jurisprudence could certainly be found, but not eleven! Yet the lectures of these hospital-schools are recognized by examining bodies, one as much as the other.

But the teaching at the eleven institutions differs widely on each subject. At one school a certain subject is handled well, at another but indifferently, while with another subject the reverse occurs. Yet the student must take the lecturer as he stands, it being practically impossible (if not invidious) to attend that particular class at another school. If he can command the funds, he goes to some private teacher, who "grinds him up" on it. If he cannot afford to do this, he scrambles along as best he can. The number of schools in London is too great for the lecturers of each to be strong all round. Some are good, some are indifferent. If three sets could be rolled together and the best men picked out, then a competent lot could no doubt be found; and a very good thing this would be for all concerned. If there were four teaching hospitals instead of eleven, there would be far better courses of lectures delivered. Perhaps this would not be the opinion of all the present lecturers, but most would admit it. If there were only two lecturers or professors on each subject, it would be better still. A man then would be required to manifest some fitness for his vocation before entering upon it. As it is, at most of the schools, on many subjects a lecturer must be found when the man in office gets weary of it. How is this done? Either some junior has been working up the subject in the expectation of getting the lectureship, which is usually the case where the post is worth having, or, if the post be worth little, some man connected with the hospital is induced to fill the vacancy. He takes it to oblige his colleagues, in the hope of getting something more congenial to his tastes at a later day.

Looked at from this point of view, the selection of teachers in the Metropolitan schools is about as wretchedly irrational as any plan that fatuity could devise. It is a truly happy-go-lucky system; and inviting candidates to come forward for a vacant post and then letting them draw lots among themselves to decide the matter would be infinitely preferable, as more likely to secure a man both competent and willing to discharge its duties. That the present system is bad and undesirable is admitted, but the whole thing is too cumbrous to be readily dealt with. The plan of holding various lectureships in rotation is the potential worst. A man may have become quite competent to teach on one subject when the opportunity comes for his advancement, and a teacher of recognized capacity and complete fitness to teach pathology passes on from a place which he fills well to the chair of materia medica and therapeutics, for which he shows no special aptitude. Whether this is an advantage or otherwise to the school and all concerned, fortunately, it is not for me to pronounce judgment.

Then there is another aspect of this multiple teaching which is a very painful one to dwell upon. My information has come directly from the students themselves: if what I am going to say is untrue, I should be glad to know it. They complain that on several subjects at certain schools the lecturers are insufficient for the examination-table, and the student must get the desired information somewhere. If he is possessed of means, he can purchase it from some of the junior members of the staff who have private classes; if not, he must do as he can. If a teaching university of London would remove such a blot on medicine as this, and do away with such a scandal, it should be earnestly prayed for by all who wish the profession well. So far as medicine is concerned, a teaching university would be a boon.

J. Milner Fothergill.

*

Œsophagotomy for Removal of Artificial Teeth.—At the Middlesex Hospital in London, last month, a patient was admitted who had swallowed a plate to which were fastened four front teeth. Mr. Lawson was obliged to remove it by opening the œsophagus below the cricoid cartilage. The patient is making a satisfactory recovery.

CHICAGO.

ACTINOMYCOSIS or not actinomycosis, that's the question which just now agitates several members of the profession residing here. Dr. Murphy claims to have had two cases of this rare disease in the course of a few months. To verify his diagnosis he called in aid Dr. Fenger, Dr. Belfield, and others, and they finally agreed that the cases were strongly characteristic of the disease. Doubters have been by no means wanting, and several claim that the cases were nothing more than simple abscess. A few of the unconvinced state that they had opportunity for microscopical examination under as favorable circumstances as those enjoyed by others.

The paper read by Dr. Murphy before the Chicago Medical Society gave an interesting account of his cases, but there was wanting that clinching argument, ocular demonstration. The only slide shown prepared from the contents of the tumor in one case failed to show the actinomyces.

The discussion which followed showed that the minds of many present were not satisfied, notwithstanding that the reporter had seen the fungus in specimens prepared from his cases. The Chicago correspondent of the *Boston Medical and Surgical Journal* has taken up the defence of those claiming the genuineness of the disease in these two cases. The editor of the *Medical Review* has taken strong ground in opposition, and a warm discussion is likely to pass through at least two or three of the journals.

The biennial reports of our hospitals for the insane have been issued, and show the same dearth of interesting information. The reports of the commissioners consist of little more than a statement of expenditure and an estimate of needs for the future. The medical superintendents give a brief statement of general condition of patients. Altogether, these pamphlets form a striking contrast to the reports issued by some of the English asylums.

It would appear that our institutions for the insane are making very slow progress in the systematic study of this class of diseases. Instead of giving, as one of the reporters does, a tabulated statement showing the rapid reduction of alcoholic stimulants consumed by patients to a quantity that barely permits of their use at all, why has he not given some information as regards the use of hypnotics and narcotics? The statement is made that mechanical restraint has been reduced to a minimum, and that certain forms have been abolished,—*i.e.*, "the muff;" but the writer goes on to say that the leather "mittens" are occasionally used, the difference being little more than in name. And again he says, "We have discarded the use of the camisole as barbarous, but the 'continuous sleeve' is sometimes used." This is another fine distinction. The reporter begins: "The insane have certain rights, among which is the right to be protected from self-injury while under the influence of suicidal impulses, and to be restrained from injuring others during attacks of homicidal mania or while under the influence of impulses to destroy clothing and other property." This is merely an argument for the perpetuation of mechanical restraint, and is not a justification. Where the use of this form of restraint ends and its abuse begins it is difficult to say. We know that in some English institutions it has been entirely done away with, and there is no reason why it might not be as radically treated as is the reduction of alcoholics. The mere enumeration of the varieties of mechanical restraint in use in some of our State institutions is sufficient to show how hard it is for our medical superintendents to radically reform this abuse. The portion of the report treating of employment for the insane is not new; nevertheless it is good, and were it properly put in practice it would probably facilitate the placing of our hospitals for the insane upon that higher plane where now stand the English institutions as regards mechanical restraint. The pathology of insanity has not as yet received any valuable additions from our institutions, nor is it likely to in the immediate future, if one may judge from present appearances.

On the morning of the 19th instant an important part of the Northern Hospital for the Insane at Kankakee was destroyed by fire, seventeen patients being consumed in the flames. To faulty construction and want of means for controlling fire, at least in part, this terrible disaster may be charged.

The readers of the *Chicago Medical Journal and Examiner* will regret to learn of the retirement of Dr. James Nevins Hyde from the position of editor-in-chief.

The health of the city has been fairly good during the early part of the winter. Typhoid fever has prevailed to an increased extent in some sections. M.

CHICAGO, January 20, 1885.

PROCEEDINGS OF SOCIETIES.

NEW YORK ACADEMY OF MEDICINE.

ANNUAL meeting, January 15, 1885, FORDYCE BARKER, M.D., LL.D., President, in the chair.

Before proceeding to the scientific business of the evening, the annual reports of officers were read and officers elected, among others Dr. A. JACOBI for President and Dr. C. C. LEE for Vice-President.

THE COMMA-BACILLUS.

Dr. E. C. WENDT made a few remarks regarding the relation of the comma-bacillus

to Asiatic cholera, and exhibited some specimens of the microbe received from Dr. Koch.

AN OBSTETRIC FORCEPS AND A VAGINAL SPECULUM

were presented by Dr. W. D. SCHUYLER, who briefly explained the advantages of the instruments, that of the forceps relating to the short cephalic and marked pelvic curves. For a full description of the forceps he referred to the *New York Medical Journal*, March 4, 1884, and of the speculum, to the same journal, September, 1876.

Dr. F. A. CASTLE called attention to the fact that the instrument-makers had so modified the shape of Nott's speculum that the principles upon which the original instrument was constructed could no longer be recognized.

DISEASES OF FALLOPIAN TUBES; THEIR RELATIONS TO UTERINE DISPLACEMENTS AND THE USE OF PESSARIES.

Dr. W. GILL WYLIE read a paper with this title. Since May, 1883, he had operated in fourteen cases for disease of the Fallopian tubes,—in nine cases in Bellevue Hospital, and in five in private practice. Twelve patients recovered; two died of septicæmia on the fifth day after the operation. Eight were cases of pyo-salpinx, two of hydro-salpinx, and four of catarrh of the tubes with peritoneal adhesions. With one or two exceptions, there were extensive adhesions, local peritonitis, and the ovaries were either diseased or more or less covered with adhesions. Short histories were given of fourteen of the cases, and twelve specimens presented, together with the report of the microscopist, Dr. H. C. Coe, at the New York Pathological Society, January 14.

On account of the lateness of the hour, Dr. Wylie read only some of the more important points in his paper. With regard to the etiology, he said that anything which can cause endometritis may also induce disease of the Fallopian tubes, and it is probable that most cases of salpingitis were due to direct extension of disease from the lining membrane of the uterus to that of the tube. In virgins salpingitis is comparatively rare, except from catarrhal disease. In the imperfectly developed and delicate the mucous membrane of the uterus is an easy prey to catarrhal disease, which may extend up into the tubes. Tubercular disease might also attack the Fallopian tubes. Many of the medical profession look upon gonorrhœa in women as a very trivial disease, probably because, unlike in the male, it does not cause urethral constriction. There can be no doubt that gonorrhœa is a very frequent, and in many instances an unsuspected, cause of salpingitis. When once it enters the uterus it cannot be safely treated locally until after it has become subacute, because of the danger of causing localized peritonitis. Specific endometritis will in many instances, although treated with the greatest care, cause salpingitis and local peritonitis. It may end in pyo-salpinx, but usually the tube becomes distended from constriction of the proximal extremity, and the poison is liable to extend to the surrounding tissues. Syphilis might cause salpingitis, as it does otitis and ozæna. Septic poisons after abortion or labor are frequent causes of salpingitis; and obstructed effete matter within the uterus may be forced into the tubes by contraction of the uterine fibres.

Local peritonitis is much more common upon the posterior than upon the anterior surface of the broad ligaments, because the tubes open upon the posterior surface. His experience led him to attach much more importance to local peritonitis than to local cellulitis: indeed, he did not believe in so-called chronic cellulitis.

Diseased tubes are very commonly associated with diseased ovaries, and in most instances the disease of the tubes precedes that of the ovaries. When there is ovaritis, it may be regarded as due to extension of disease from the tubes and peritoneum. There are, however, certain diseases of the ovaries, as cancer, which may cause secondary disease of the tubes. In hystero-epilepsy and hysteria he expected to find a cystic or atrophied ovary following catarrh of the tubes. Hemorrhage into the tubes, and the presence of other fluids, may cause more or less permanent distention.

The subjective symptoms are so varied, and salpingitis is so frequently associated with uterine diseases, that it is often overlooked or not distinctly made out. The most important subjective symptom was pain in the iliac region, which is more marked in pyo-salpinx than in hydro-salpinx or catarrh of the tubes. Pyo-salpinx, especially if accompanied by abscess around the tube, causes marked local pain and, usually, more or less tenderness.

The objective symptoms up to a recent date were regarded as only imperfectly clearing up the diagnosis, but Dr. Wylie thought that by allowing an acute case to become more or less subacute, and then introducing cotton pledgets containing glycerin and alum around the cervix two or three times a week, within from three to six weeks the condition of the parts would have become so changed as to permit of a positive diagnosis in almost every case in which there was disease of the tubes or ovaries, especially if the patient were examined under ether.

With regard to the pathology, an accurate account of it is scarcely to be found except in the German. The difference in the shape, size, and position of the mucous canal of the Fallopian tube and that of the uterus causes a marked difference in the result of the same disease in the two localities. Inflammation

of the endometrium, producing enlargement of the uterus, may of itself cause displacement, imperfect drainage, and parametritis, but this is not the rule. Moreover, the uterus is accessible and amenable to local treatment, whereas a like inflammation of the lining membrane of the tube is not accessible, is almost certain to result in prolapsus of the tube, obstruction of the inlet causing imperfect drainage, and peri-salpingitis from emptying of the contents into the peritoneum. Salpingitis nearly always becomes chronic, in many instances lasting as long as the patient. The first effect of the disease reaching the tube is to cause it to become engorged with blood, to sink lower in the pelvis, and, as salpingitis is nearly always associated with an enlarged uterus, this organ also will sink, and, as the patient in the acute stage lies upon the back, the fundus is thrown backward by gravity, the peritoneum becomes inflamed, lymph is thrown out and glues the different organs together, and, as the acute stage subsides, draws them out of their normal position; the twisted broad ligament then holds the uterus in the position of retroversion. The organ may sink lower, being drawn down by contracting adhesions, and perhaps become retroflexed. The tubes, contracting, may also become strong cords, binding the uterus firmly in the position of retroversion. This fixation of the tissues may be so marked that any attempt to lift the uterus and hold it up by pessaries would cause rupture of the tube and emptying of its septic or irritating contents into the peritoneal cavity. By proper treatment in time we might be able to replace the fundus, but to keep it replaced is the greatest difficulty. If but one tube were affected, the retroversion would be less marked, and the organ might be drawn toward the affected side. When but one side is the seat of disease, it is usually the left.

The character of the fluid contained within the tubes varies; it may be transparent water, milky, thick, greenish, or broken-down pus. In the majority of his cases the tubes are infiltrated with pus and serum, and in some instances the tissues become so rotten that the ligatures cut through the degenerated stump. In some the tissues were not sufficiently contracted to enable the ligature easily to grasp the stump. The most common affection of the ovary, if it were diseased at all, is cystic degeneration. Superficial cysts with thin fluid are commonly found, but deep-seated, central cysts might fairly be called degeneration, and it was to these that he referred in speaking of cystic degeneration of the ovaries.

Treatment.—In cases in which there are adhesions and we are not allowed to operate, he would not resort to the use of pessaries, hoping to replace the uterus and keep it there by such supports; he would be satisfied if he could render the uterus movable, and thus improve the whole general circulation of the pelvic organs, thereby giving the patient more relief than if any attempt had been made to employ pessaries. He had succeeded in tapping in two or three cases in which he was not allowed to operate, and in one of the cases a cure was effected. But it was believed that the enlargement was an abscess formed in an old hæmatocele. The other two patients were benefited, but not cured. When disease of the tubes can be clearly recognized, the patient is bedridden; complete removal of the tubes and ovaries alone would give relief.

In the operation, the abdominal opening should not ordinarily be made greater than the width of the three fingers, admitting only two,—thus guarding against ventral hernia. It is important for the same reason, in closing the wound, to obtain perfect apposition of the fascia as well as of the peritoneal surfaces. He usually gives the patients pancreatized milk during the four or five days preceding the operation, to guard against distention of the gut from gas. If the omentum appear to be formidably adherent, by passing two fingers down through the opening and moving them from side to side, one would be enabled easily to tear away the adhesions. It might, however, be necessary in some cases to tie the omentum below and above and cut a part away. In order to get at the ovary directly and to obtain a suitable pedicle, the broad ligaments should be unrolled.

Dr. E. NOEGGERATH was asked to open the discussion. He repeated what had been stated at the last meeting of the International Medical Congress, that to call this Tait's operation was a misnomer, for Hegar had performed the operation in forty-two cases before Tait's experience was known. Regarding gonorrhœa as a cause of salpingitis, he had made special studies in Berlin to establish the gonococcus, but the gonococcus was a diplococcus, and no gelatin had been obtained in which it could be raised beyond the second or third generation. If dislocation of the uterus was to be considered the result of salpingitis and peritonitis, he would have to repeat what he said in 1872, that the form of dislocation was latero-version combined with anteversion. He did not doubt that Dr. Wylie had seen cases in which a sufficient amount of plastic material had been thrown out to carry the uterus backward, but such cases were exceptions. In ninety per cent. of the cases of retroversion he thought the uterus could be replaced and kept there by instruments, and the cases in which we could not replace it because of posterior adhesions were very rare. In other words, a large percentage of retroversions are not accompanied by adhesions.

As to the diagnosis of salpingitis, those cases in which there is ordinary salpingitis with very slight exudation should be considered

apart from those in which there was salpingitis in its later stage, pyo- or hydro-salpinx already present. In the first place, it is not necessary to feel the tubes at all in order to make a diagnosis. If there is perimetritis with catarrh, with minute condylomata about the hymen and labia minora, we know that there is also salpingitis, because the cases in which perimetritis exists without salpingitis are extremely rare.

With regard to the surgical diagnosis in case an operation were proposed, it is the shape of the tumor that is of the greatest importance. The tumor of salpingitis is very often not single, but divided into two or three sections, having the shape of a cone running in the direction of the lateral diameter of the pelvis. He believed, with Dr. Wylie, that in the extreme cases referred to no treatment other than an operation would prove successful. But the large majority of cases of salpingitis are not ready for an operation, and something else must be done. The treatment here would be very much like that described by the author of the paper; but that which he had found most efficient was the use of the waters of Franzensbad, of Bohemia.

Dr. A. J. C. SKENE said that, so far as his observation went, it is rare to see disease of the Fallopian tubes not preceded by gonorrhœa. But he differed from Dr. Noeggerath in his statement that we rarely see pelvic peritonitis without disease of the tubes.

In the diagnosis the practical difficulty seemed to him to be to distinguish between a small ovarian cyst more or less prolapsed and pyo- or hydro-salpinx. He would inquire what might be the value of aspiration in diagnosis. If we find ciliated epithelium so generally present in pyo- and hydro-salpinx, what objection could there be to the removal of a portion of the fluid and examining it for diagnostic purposes? Out of twenty-one specimens which he had examined, eighteen contained ciliated epithelial cells, indicating that this condition was present.

As to treatment, it had been well remarked that many patients are operated upon before other means had been exhausted. He thought that if a hydro-salpinx were aspirated the fluid might not reaccumulate, and the patient would recover.

Dr. P. F. MUNDÉ said that since he had begun the study of this subject, some years ago, the greatest difficulty which he had met was in the diagnosis of these cases of salpingitis. The cases which most require an operation, the cases in which the swelling in the pelvic cavity consists of a diffuse fulness, he had always found the most difficult of diagnosis. He doubted whether we should be able to make a *positive* diagnosis until after laparotomy had been performed. As regards the influence of inflammation of the tubes upon displacement of the uterus, he was disposed to agree with Dr. Noeggerath in his views of lateral displacements and some anterior displacements; but he had also seen some cases in which the uterus was retroverted, bound down, and accompanied by marked salpingitis. He was rather disposed to think that they are as common as lateral and more common than anterior displacements. He agreed with Dr. Noeggerath that in the majority of cases of retroversion the uterus is not adherent. So far as treatment was concerned other than laparotomy, he thought we can do but very little. There had been certain cases of diffuse swelling in which he had given the patient relief from pain by means of the galvanic battery.

Dr. WYLIE, in closing the discussion, said he was satisfied that if Dr. Mundé would adopt his preparatory treatment he would also be able to map out the exact condition of the pelvic organs in cases of salpingitis, and so decide as to the necessity of an operation. As to treatment by aspiration, he thought it would require more than a withdrawal of the fluid to effect a cure: it would also be necessary to have perfect drainage. In cases demanding an operation he thought the rule not to tap any abdominal tumor in a case in which it was intended to perform laparotomy should be observed. With regard to retroversion associated with salpingitis, his experience had been that in women who had never borne children lateral version or anterior version is common, but in the majority of cases of women who have borne children there is retroversion, and especially so if the salpingitis be due to septic endometritis extending to the tubes.

STATE BOARD OF MEDICAL EXAMINERS.

Dr. C. C. LEE, Chairman of the Committee on Education, reported that, after a full and careful consideration of the resolutions (on proposed State Board of Medical Examiners) referred to it at the last meeting of the Academy, the committee deems it inexpedient for the Academy of Medicine to take any action at present in regard to the establishment of a State Board of Examiners for the granting of license to practitioners of medicine in this State. The report was accepted.

Dr. F. R. STURGIS made some remarks upon the importance of having the licensing power to practise medicine separate from the teaching power, and asked that the Academy adopt resolutions expressing its belief that the best interests of the public and medical profession would be served by the passage by the Legislature of a bill appointing a State Board of Examiners, and that its delegates to the State Society be instructed to support the passage of such a bill.

After some remarks by Dr. Roosa, Dr. Hanks, and the President, Dr. Sturgis consented to laying the resolutions on the table at present, expecting that they would be acted upon at a future meeting.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, January 8, 1885.

The President, Dr. SHAKESPEARE, in the chair.

A NUMBER of specimens were exhibited at the opening of the meeting.

Primary tumor of the liver in a child nine months old.

Aortic valvular disease with rupture of one of the leaflets.

Malignant tumor of the kidney.

A large renal cyst. The foregoing were all presented by Dr. SHAKESPEARE.*

Sarcoma of the clavicle. Presented by Dr. G. E. DE SCHWEINITZ.

This specimen was sent to me by Dr. John Ashhurst for microscopical examination, and he kindly gives me permission to exhibit it to-night. The tumor occurred in the person of a young girl, S. L. B., aged 16, who came to him for treatment last August. She was a somewhat frail-looking, clear-skinned blonde, whose general health up to the time of the appearance of the growth had been satisfactory. The family history was good; none of the other five children composing the family presented any similar affection, nor was there any history of tumor for two generations back. The tumor began at the left sterno-clavicular joint as a small nut-shaped swelling, having arisen without known inflammatory or traumatic origin, although, as the father stated, they always believed that the patient had in some way and unknown to herself received an injury at this point. The growth of the tumor was rapid, and at the end of five months stood out as a prominent swelling, as large as an orange, occupying the inner two-thirds of the clavicle, and was covered by somewhat reddened and thinned skin. Pain, although not constant, was at times a very severe symptom. On the 7th of last August Prof. Ashhurst removed the growth, together with the inner two-thirds or three-fourths of the clavicle. Examination of the gross specimen shows it to be a spindle-shaped growth, about four inches long, three inches at its greatest breadth, and two inches deep, which has taken its origin in the medullary cavity of the bone gradually, and become surrounded by a firm fibrous or periosteous capsule. The true tumor-tissue is of moderate consistence and reddish-brown color. Microscopic examination reveals the following points of interest. The capsule is composed of dense fibrous tissue, from which prolongations pass, dividing the tumor into numerous spaces which are filled with small round sarcoma-cells. These spaces are in many places again divided by a delicate spindle-shaped tissue into small alveoli. In addition to the round cells, spindle-shaped cells are also seen in spots; giant-cells are absent, or at least only a few multinucleated cells, relegated to the regions of the spindle-cells, are noted. The tumor, I think, should be classified as a small round-celled sarcoma, with an alveolar arrangement. If this tumor be accepted as a variety of alveolar sarcoma, it is somewhat unusual. Twice before specimens of alveolar sarcomata of the long bones have been exhibited to this Society,—one of the femur, by Dr. Nancrede, and one of the knee-joint, by Dr. Formad. At that time Dr. Formad thought the variety of the sarcoma justified a rather more favorable prognosis than usual, while Dr. S. W. Gross, during the discussion, after referring to the somewhat unusual microscopical character of the tumor, thought the outlook for the patient was bad, as this variety of sarcoma is peculiarly fatal. Dr. Formad's prognosis was correct, because in that instance the patient was alive and well, if I am not mistaken, for some time after the operation, and may be now, for aught that I know. In regard to the result of the present case, I am able to speak quite definitely. Although the operation was successful and the removal of the growth quite complete, the hemorrhage insignificant, and the recovery of the patient satisfactory, in about two months after the operation the growth reappeared either in the old wound or about two ribs lower. In this case, then, the truth of Dr. S. W. Gross's remarks have been only too thoroughly proved.

Dr. SHAKESPEARE said that this specimen was of interest on account of the rarity with which similar ones had been presented to this Society. Through the kindness of Dr. De Schweinitz he had the opportunity of examining sections from the growth, and he thoroughly agreed with the exhibitor as to its nature.

Dr. SIMES had also examined microscopic sections, and endorsed the statements made by the preceding speaker.

Alveolar sarcoma of the kidney. Presented by Dr. M. LONGSTRETH.

The patient, J. E., æt. 9 months, was first under the care of Dr. McOscar,—to whom I am indebted for the specimens and this history,—suffering from an attack of summer-complaint. The patient was at that time three months old, and had been ill for a week or two. He was in a state of great emaciation, and, upon examination of the abdomen, a swelling was found in the right flank. The little patient recovered from the bowel-trouble, but the general condition did not materially improve. During the remaining six months of life the child was only occasionally under observation, and at those times suffered from paroxysms of pain, apparently in connection

* The notes of the above cases have been withheld for future publication, and, in consequence, the interesting discussion upon them, in conjunction with the case presented by Dr. M. Longstreth, must also for the present remain unpublished.—RECORDER.

with the tumor. The bulk of the tumor, as felt through the abdominal wall, did not seem to increase greatly up to his death. The urine was not carefully inspected. Three days before death the pain increased to great violence, and in this condition death came. The post-mortem examination showed the enlarged right kidney more firmly adherent to the posterior abdominal wall and to the ascending colon and mesentery, as well as portions of the small intestine attached to its anterior surface. The diseased organ weighed fifty-two ounces, and presented itself as a rounded, slightly oval mass, regular in outline, smooth of surface, and with a moderately firm, elastic consistence. The capsular surface was pretty dense, of shining whiteness, with conspicuous small vessels passing over it. On section—which measured three and one-half inches by three inches in the two diameters—the tissue presented a very varied appearance. In parts it was of a dense white, perfectly homogeneous aspect; in others, the pinkish-white mass showed streaks of yellow, with numerous small spots of red, and there were also large blood-red areas. In other parts the tissue was breaking down into cysts, of which several large ones were present, the largest of the size of an English walnut. The cysts were all situated on the periphery of the mass, but they did not cause any protrusion of the capsule. At the upper extremity of the mass there was found a portion of kidney-tissue not invaded by the new formation. On section, this portion occupied about half an inch of the long diameter of the mass, and was seen to be separated from the new growth by a thin partition of connective tissue; externally it showed itself like a lobule of kidney, fitting like a cap on the spherical tumor, as does the suprarenal capsule on the kidney itself. The microscopical examination showed the new formation to be a small round-celled sarcoma. The greater portion of all sections presented cells nearly rounded in figure, embedded in a perfectly homogeneous basis-substance. The uniform area of cells was, however, interrupted by streaks of spindle-cells, running in narrow bands, enclosing greater or less areas of round-cell tissue. These circumscribing bands of spindle-cells sometimes formed circular areas looking like the cross-section of a tube; in other places the bands pursued a very tortuous course, resembling the outline of a twisting, undulating tube cut in a longitudinal direction. The bands of spindle-cells were never of great breadth, rarely more than four or five spindles. The spindle-cells were not regularly or closely fitted, but were embedded, like the round-cell elements, in a homogeneous basis-substance. In the spindle-cell bands there were occasionally seen fine capillaries filled with red blood-corpuscles, which sometimes ran along for a considerable length; many other capillaries were seen cut transversely or obliquely, also in the spindle-cell tissue many areas of hemorrhage were visible. In many places a scanty fibrillar tissue, with various-shaped nuclei, oval, angular, and spindle, was seen. This tissue was thrust in and filled the interstices between the areas of round cells circumscribed by the spindle-cell tissue. Thus, in the section one passed from areas of round cells to the narrow bands of circumscribing spindles, and then into fibrillar tissue with open meshes, apparently without any intercellular basis-substance. The whole picture resembled the cortical portion of the kidney, transformed by the presence of a new growth; the lumina of the convoluted tubes, greatly enlarged, were filled with a round-celled homogeneous basis-substance tissue, the base-membrane of tubes transformed into spindle-cell bands, and finally areas of hyperplastic, intertubular connective tissue, in which, or along the basement-membrane of the tubes (spindle-cell bands), ran the intertubular capillaries. The left kidney weighed five ounces. On section, it presented a normal aspect; the capsule separated easily, was not thickened, and the surface of the kidney remained smooth. The microscope showed no alteration of its tissues. The liver was large, smooth, blunt-edged, pale; under the microscope a very high degree of fatty infiltration was found. The other organs showed nothing especial to note. No secondary new formations were found.

NEW YORK PATHOLOGICAL SOCIETY.

ANNUAL MEETING, JANUARY 14, 1885.

The President, GEORGE F. SHRADY, M.D., in the chair.

FOURTEEN CASES OF TAIT'S OPERATION.

DR. W. GILL WYLIE presented twelve specimens, and related the histories of fourteen cases in which he had performed laparotomy for the removal of the tubes and ovaries for salpingitis. The histories were accompanied by the report of the microscopist, Dr. H. C. Coe. The cases formed the basis of a paper on "Diseases of the Fallopian Tubes; Their Relations to Uterine Displacements and the Use of Pessaries," an account of which will be found in our report of the New York Academy of Medicine meeting of January 15 (see page 362).

Dr. JOHN A. WYETH presented a patient showing the result of an operation upon the lower jaw, reported at the last meeting. He also briefly referred to a case in which he performed an operation upon the jaw after anæsthetizing the parts by hydrochlorate of cocaine. The patient felt no pain whatever during the continuance of the operation.

Among the officers elected for the ensuing year were Dr. John A. Wyeth for President and Dr. George F. Peabody for Vice-President.

PHILADELPHIA CLINICAL SOCIETY.

AT a stated meeting held December 26, 1884, Dr. HENRY BEATES, Jr., in the chair, Dr. JAS. B. WALKER reported a case of "Ulcer of the Stomach." (See page 348.)

DISCUSSION.

Dr. A. V. SCOTT had used rectal alimentation in a similar case with success. Cinchonidia sulph., in twenty-grain doses, was given with the food.

Dr. E. E. MONTGOMERY did not hear the whole report of the case, but was reminded by the concluding remarks of two cases seen the previous year. The first was an old gentleman suffering with gastric catarrh and gastralgia, the latter appearing both before and after meals. Under rigid diet the pain after food-ingestion was controlled, but that occurring during the empty condition was not lessened. Food was taken frequently. After several months of suffering, the patient was carried off by an attack of pleuro-pneumonia. The post-mortem appearances indicated commencing carcinoma. The kidneys were not granular.

The other case was confined to bed six months with constant vomiting of food in a sour condition. All food was rejected with impartiality. Dr. Bartholow, being called in consultation, found evidences of specific lesions, which had been denied by the patient. After using mercurials in vain, however, another consultation developed the suspicion that we had a case of hysterical vomiting to deal with, and under appropriate treatment the patient quickly recovered.

Dr. L. BREWER HALL desired to bear testimony to the value of turpentine in hemorrhage of the stomach. The good results of its use are immediate, and it is also of value in pulmonary hemorrhages. The oil of erigeron may be used instead, and is more acceptable to the taste.

Dr. HENRY BEATES, JR., asked Dr. Walker if he still looked upon the micaceous appearances of the skin as an evidence of carcinoma, and, if so, if it would not have been of service in the diagnosis of one of the cases related.

Dr. WALKER, in closing the discussion, said he had seen but two cases with the micaceous skin which were not carcinomatous, one being a case of pernicious anæmia. He looked upon it as only confirmatory. The use of oil of erigeron as a pleasant substitute for turpentine as a hæmostatic was suggested by the late Dr. Geo. B. Wood, but the accuracy of taste of the suggester was doubted. The speaker had taken a dose of it on a patient's complaint several years ago, and had not recovered from it yet.

In the cases simulating gastric ulcer the resemblance is interesting. The ejecta are more frequently sweet than acid in such cases. In unsuspected cases of carcinoma in plethoric subjects the peculiar appearance of the skin alluded to may be the only indication present of the real nature of the case.

As regards Dr. Scott's case, the course pursued seemed to embody all that was necessary. Total rest of the affected organ is generally sufficient. The bismuth may be useful.

AT the stated meeting held January 23, 1885, the annual election of officers resulted as follows:

President, Dr. Edward E. Montgomery.
First Vice-President, Dr. John B. Roberts.
Second Vice-President, Dr. Amy S. Barton.
Corresponding Secretary, Dr. Ida E. Richardson.
Recording Secretary, Dr. I. G. Heilman.
Reporting Secretary, Dr. Mary Willits.
Treasurer, Dr. L. Brewer Hall.
Councillors, Dr. James B. Walker, Dr. Daniel Longaker, Dr. Clara Marshall, Dr. Henry Beates, Dr. Henry Leffmann.

REVIEWS AND BOOK NOTICES.

A SYSTEM OF PRACTICAL MEDICINE BY AMERICAN AUTHORS. Edited by WILLIAM PEPPER, M.D.; assisted by LOUIS STARR, M.D. Vol. I.—PATHOLOGY AND GENERAL DISEASES. Philadelphia, Lea, Brothers & Co., 1885. For sale by subscription only. 8vo. Cloth, $5.00; leather, $6.00; half Russia, $7.00.

It is with pleasure that we notice the appearance of the first volume of "A System of Practical Medicine by American Authors," under the able editorship of the distinguished Professor of Theory and Practice and of Clinical Medicine in the University of Pennsylvania. The selection of authors has been judiciously restricted to American physicians of acknowledged ability, not ignoring the importance of the study of special subjects by European investigators, to which full justice is done and of which due acknowledgment is made, but because it was felt that a proper time had arrived for the presentation of the whole field of medicine as it is actually taught and practised by its best representatives in this country. The publication of a work of such character and aim deserves especial notice by the profession, and it may almost be said to mark an epoch in American medicine. In reply to the query, Who reads an American book? we may answer, "Everybody, but particularly Americans."

The design of the work is comprehensive: it will be completed in five volumes, discussing the usual topics of internal medicine, including gynæcology and other special departments, containing about eleven hundred pages each, with illustrations. The next two volumes will appear at intervals of about four months.

The volume before us contains the following articles:

General Morbid Processes, by Reginald H. Fitz, M.D.; *General Etiology*, *Medical Diagnosis, and Prognosis*, by Henry Hartshorne, M.D., LL.D.; *Hygiene*, by John S. Billings, A.M., M.D., LL.D. (Edin.); *Drainage and Sewerage in their Hygienic Relations*, by Geo. E. Waring, Jr., M. Inst. C. E.; *Simple Continued Fever*, *Typhoid Fever*, *Typhus Fever*, by James H. Hutchinson, M.D.; *Relapsing Fever*, by William Pepper, M.D., LL.D.; *Variola*, by James Nevins Hyde, M.D.; *Vaccinia*, by Frank P. Foster, M.D.; *Varicella*, by James Nevins Hyde, M.D.; *Scarlet Fever*, by J. Lewis Smith, M.D.; *Rubeola*, *Rotheln*, by W. A. Hardaway, A.M., M.D.; *Malarial Fevers*, by Samuel M. Bemiss, M.D.; *Parotitis*, by John M. Keating, M.D.; *Erysipelas*, by James Nevins Hyde, M.D.; *Yellow Fever*, by Samuel M. Bemiss, M.D.; *Diphtheria*, by Abraham Jacobi, M.D.; *Cholera*, by Alfred Stillé, M.D., LL.D.; *Plague*, by James C. Wilson, A.M., M.D.; *Leprosy*, by James C. White, M.D.; *Epidemic Cerebro-Spinal Meningitis*, by A. Stillé, M.D., LL.D.; *Pertussis*, by John M. Keating, M.D.; *Influenza*, by James C. Wilson, A.M., M.D.; *Dengue*, by H. D. Schmidt, M.D.; *Rabies and Hydrophobia*, *Glanders and Farcy*, *Anthrax* (*Malignant Pustule*), by James Law, F.R.C.V.S.; *Pyæmia and Septicæmia*, by B. A. Watson, A.M., M.D.; *Puerperal Fever*, by William T. Lusk, M.D.; and *Beriberi*, by Duane B. Simmons, M.D.

After a careful examination of its pages, it may be said, as a criticism upon the work, that it has been ably conceived, and thus far has been admirably executed; it is also worthy of note that the press-work and binding are exceptionally good, and in keeping with the high character of the contents. Everywhere through its pages are found references to current medical literature, both indigenous and foreign, showing that the authors are fully abreast of modern progress, and have contributed to make this System truly representative not so much of American medicine as it is of modern medical science as understood and taught by American authors.

THE STORY OF MY LIFE. By J. MARION SIMS, M.D., LL.D. Edited by his Son, H. MARION SIMS, M.D. New York, D. Appleton & Co., 1884. 12mo, cloth, pp. 471. $1.50.

Autobiographies usually tell both too little and too much; they tell too little of what we desire to know of the man himself, and communicate some things that we do not care to hear. This charge can be made with less truth about this volume than about most of such publications. In a simple, unaffected style the eminent author lays before us an account of his early difficulties, his school-days, his courtship, his struggles with adversity and ill health, his discoveries, and, finally, his crowning success in life,—the organization of the Woman's Hospital, New York, which remains a perpetual monument to his skill, his energy, and his industry. The career of Marion Sims, told in graceful language which at times is pathetic, shows how a great mind, —though hampered by obscurity of birth, a delicate physical frame, frequent sickness, adversity and misfortune,—conquering every obstacle, can finally rise superior to them all. He attributes all his after-achievements to his early principles of honesty, industry, and a determination to succeed. This, with directness of purpose and an untiring sleuth-hound sort of persistency in following an idea to its logical and practical conclusion, enabled him to develop step by step as his life-work gradually opened before him, until he became, in his department of surgery, the leading man of his day. The references to his relations with contemporaneous physicians of New York, England, and France are not the least interesting part of the book.

Dr. Sims was a warm-hearted man, who feared God and loved his family and was true to his friends. His letters to his wife contained in the Appendix reveal his tenderness and his regard for her and their children in a very touching manner; but it seems like prying into the private correspondence of a friend, and almost makes one feel, in reading them, as if doing a mean or dishonorable thing. Among the last words which he wrote were those in which he ascribed his happiness, not to his successful career as a surgeon, but to his congenial home-life. After describing the great unhappiness of Trousseau, due to the conduct of his family, he declares, "We are happy in this life as our children choose to make us. The joys, amenities, and pleasures of home, with health, make life worth living. But these must abound and be enjoyed by all who come in contact with us. We must not only be happy in our own homes, but must do all the good we can outside of these, and try to make others happy too."

This life-story, we hope, will be read and enjoyed by our readers for themselves. It is full of encouragement and healthy stimulus to increased activity in professional work, and indicates the way to true success in life.

GLEANINGS FROM EXCHANGES.

DR. KOCH AND HIS CRITICS.—Dr. Koch has published a reply to some of the objections which have been raised by his statement that he has "discovered the cause of cholera" in the so-called "comma-bacillus." Dr. Koch endeavors to deal with the objections of those who point to the fact that he is false to the principles laid down by himself, in

so many words, at an earlier period of his career as a bacteriologist. Dr. Koch *formerly* stated (and all men of a scientific habit of mind must agree with that statement) that no micro-organism could be justly declared to be the cause of a disease until the organism had been "purely cultivated" and the disease had been produced by the inoculation of a healthy animal with this "pure culture." Dr. Koch *now* calls those persons who hold this reasonable doctrine "sceptics," and in a somewhat flippant manner states that he hopes to convince them by experiments which he is *now* (too late!) conducting similar to those of Professors Reitsch and Nikati.

It is too late for Dr. Koch to convince any true scientific sceptic. The man who has rashly committed himself to such public assertions with regard to the cause of a phenomenon cannot be subsequently accepted as a witness in his own favor. As soon as Dr. Koch publicly declared on insufficient data that he had discovered the comma-bacillus as the cause of cholera, and without any reserve insisted on using his authority and position to force upon the public a mere hypothesis as though it were a demonstrated or even a highly probable conclusion, then and there Dr. Koch put himself out of court as a witness of new facts in support of his contention. Others may produce the record of experiments in order to establish Dr. Koch's hypothesis, but he himself is so terribly involved in the issue that we cannot accept his judgment on such delicate experiments as those which he now is anxious to quote in favor of his view. *Vestigia nulla retrorsum!*

In reply to Dr. T. R. Lewis, Dr. Koch apparently wishes us to believe that he knew all along of the common occurrence of "comma-bacilli" in the mouths of healthy human beings. It is difficult to believe that Dr. Koch would not previously have mentioned these normal comma-bacilli and have pointed out how they differ (if they do differ) from the cholera comma-bacilli had he been acquainted with them. Dr. Koch states that the normal comma-bacilli of the mouth differ from those of cholera in regard to the conditions favorable to their artificial cultivation. *When* did he discover this? He reproaches Dr. Lewis with not having made such artificial cultivations. *When* did Dr. Koch make such cultivations of the comma-bacilli of the mouth himself? Surely it was *his* business to show that the hypothetical cholera comma-bacillus was distinct from the closely similar comma-bacillus of the mouth. Yet we find no allusion whatever to the comma-bacilli of the mouth in Dr. Koch's reports or in the address to the Special Medical Congress in Berlin. Either Dr. Koch did not know of the existence of the comma-bacilli of the mouth or he suppressed all mention of them when he endeavored to obtain credence for his extraordinary assumption that a comma-bacillus is the cause of cholera.

There will be no difficulty in producing experiments *now* which will seem to prove that the cholera-comma and the normal mouth-comma behave differently. It will not be difficult to produce symptoms like those of cholera by injecting cholera-commas into guinea-pigs or rabbits. This kind of experiment is so delicate that it may easily be allowed to take a course favorable to the views of a prejudiced experimenter. That is the pity of it. Dr. Koch has sacrificed for a momentary notoriety the irrecoverable position of a trusted scientific observer. He *must* be for the future (he has so willed it) a prejudiced experimenter. He has the fearful responsibility on his shoulders of his premature claim to a "discovery," of his unfortunate attempt to force his shadowy hypothesis of the comma-bacillus upon Europe as a solid result of scientific method, and this must render all his work on this subject for the future rightly liable to suspicion and doubt. Though we may credit him with perfect sincerity, we can never regard him as otherwise than hopelessly biassed.—*Medical Times and Gazette.*

A Central Tumor causes Jacksonian Epilepsy.—Dr. William Osler, of the University of Pennsylvania, records in the January issue of *The American Journal of the Medical Sciences* the history of an instructive case of Jacksonian epilepsy, the main points of difference between which and true epilepsy are the slow onset, local in character, beginning in (or in mild attacks confined to) one limb or a single group of muscles; the gradual extension until the side is involved, or in severe attacks the entire body; loss of consciousness late, not early and sudden as in true epilepsy; and, lastly, the muscular contractions are clonic.

His case lasted over fourteen years, the convulsions beginning in the left hand, at first monobrachial, then extending to the leg, afterwards becoming unilateral, and finally general; at first without loss of consciousness. For the first nine years of the illness there were remarkable intermissions, lasting for six or seven months, once an entire year. Six years after the onset the leg got weak and stiff. For four years, the tenth, eleventh, twelfth, and thirteenth of the illness, the seizures were frequent. During this period there were six weeks of unconsciousness, in which the spasms were very frequent, from fifty to eighty in the day. Ten months prior to the final attacks there was freedom from convulsions. The intellectual faculties were unimpaired.

The case was unusual in the limitation of the lesion to the ascending frontal convolution and to its fasciculus of white matter, scarcely involving the gray substance, which is com-

monly affected in cortical epilepsy. The accurate localization and the remarkable absence of tissue-changes in the immediate vicinity give the case the nature of an exact physiological experiment. With this limited lesion of the motor area there was permanent paralysis with contracture of one extremity and epileptiform convulsions. Another feature of interest in the case is the light it throws on the situation of the leg-centre. The fibrous mass was situated entirely within the anterior part of the paracentral lobule, limited in extent, confined chiefly to the medullary fibres of the superior frontal fasciculus, and only touched the gray matter in places. A point to be referred to is the absence of the paralysis of the leg for the first six years; for if the convulsions and monoplegia were caused by the same lesion, how explain the late onset of the latter? From the fibroid state of the tumor it might reasonably be inferred that it was originally larger and had shrunk; but the absence of puckering on the surface, and the way in which the margins merged with the contiguous parts, make it probable that the growth was always small, so small in fact that at one period of its development it may have caused sufficient irritation to induce the convulsions, and yet at the same time not involve the special fasciculi of white fibres to the extent of producing weakness of the leg, or monoplegia.

The Relation between Sick Headache and Astigmatism.—Mr. H. Bendelack Hewetson read a paper on this subject at the Leeds and West Riding Medico-Chirurgical Society, and showed six cases, as well as related the notes of several others, in which patients of ages from 12 to 36 had been for many years the victims of periodic attacks of migraine. Between the attacks of migraine there had been chronic dyspepsia and vertigo in walking in several of the cases. Two could bring on an attack of vomiting by sewing. All had some form of astigmatism, either mixed or compound, hypermetropic or myopic. All were completely cured by wearing proper correcting cylinders constantly. Mr. Hewetson believed that, when astigmatism of an abnormal character (or in some rare cases even a simple state of hypermetropia) existed in a neurotic subject, it might be the entire cause of periodic sick headache, with its accompanying dyspepsia, and could be cured by suitable glasses constantly worn. Mr. Hewetson related Dr. Lauder Brunton's experience on this subject, but thought that the chief agent in producing this neurosis was the astigmatic element in the visual defect in most cases which had come under his notice; and it evidently had little relation to the amount of an optical defect, unless that defect were complicated by astigmatism. Astigmatism in one eye, or eyes of varying degrees of optical error, would cause the same condition in neurotic subjects.—*British Medical Journal.*

Physicians on School Boards.—At the meeting of the Vienna Public Medicine Society, Dr. Baginsky, a well-known writer on school hygiene, drew attention to the advisability of medical inspection of schools. His conclusions were as follows: that, notwithstanding the improved hygienic condition of schools, the infantile organism is still subjected to injurious influences depending on school-attendance; that improvement is for this reason not one to be intrusted to architects and pedagogues, but to be carried on on a physiological basis; that it is therefore fitting that the decision as to improvements, both as regards buildings and systems of teaching, should be submitted to the physician; that every school committee should have a physician among its members; that the activity of every school committee as a whole, and of the medical member in particular, should be continuous; that periodic revisions do not fulfil the desired aim; that absolute independent power of deciding should be permitted to no member of such a committee, either as regards changes in the form of the school or in the studies,—not even to the medical member; that any practising physician should be able to become a member of a school committee when he by examination could show his fitness for the office. The passing of the "Physikatsexamen" (a special examination for medical officers of health) would be proof of such fitness.—*Med. Press.*

Repair of Tendons after Destruction.—At a recent meeting of the Berlin Medical Society, Dr. Gluck reported on a patient whom he had shown to the Society in February, in whom the tendons of the extensor communis digitorum and the extensor indicis had been destroyed in consequence of a phlegmonous affection at the back of the hand. Dr. Gluck replaced the tendons by a plait of catgut fibres, extending from the metacarpo-phalangeal articulation to the transverse dorsal carpal ligament. The operation had succeeded perfectly, the functions of the missing tendons being now completely performed, ten months after. He also showed another patient, aged 76, on whom he had performed the same operation rather less extensively, but with equally good results. He believes that the irritation of function exerts a regenerative influence on the catgut, so that, instead of being absorbed, it becomes organized. He has tried a similar experiment with divided nerves, by stitching one extremity to each end of a decalcified bone drainage-tube, with the result that they have become united. This method has been recommended also by Dr. Vendoit, of Liège, and called by him "névrotisation du tube osseux." Dr. Gluck strongly recommends both operations.—*British Medical Journal.*

CHOLERA-PRECAUTIONS.—The dread of cholera, and the obvious necessity of taking all possible precautions against its introduction and—more fearful still—against its spread, have opened the eyes of the Viennese to a number of sanitary defects in their midst. A writer in the *Allgemeine Wiener Med. Zeitung* draws attention to the want of proper closet-accommodation, and calls upon the Stadtphysikat and all other sanitary authorities to see that there is proper provision of closed closets in all houses, and especially in public places, hotels, coffee-houses, schools, railway-stations, theatres, and generally wherever people congregate. He complains, and with truth, that accommodation in this direction is insufficient, and that the condition of the discharge-pipes in even much-frequented hotels is a deplorable one,—offensive to the guests, and dangerous to the health of the inmates. Let us hope and *make sure* that all our own closet arrangements are perfect.—*Medical Press.*

DISPOSAL OF REFUSE IN VIENNA.—One of the most important innovations during the year is the new method that has been adopted in Vienna of collecting and removing town refuse. In place of doing this in open carts as heretofore, and as, alas! is the custom in many English towns, each household is supplied with a barrel with a close-fitting lid. When this is filled, the lid is well fastened on, the barrel placed on the cart and removed to the place appointed, without the possibility of any household dust and filth, impregnated with disease-germs, being blown about, and possibly disseminating disease along the line of route. One would think that all sanitary authorities would at once take the hint and do likewise; but the ways of sanitary authorities are not our ways, nor their thoughts our thoughts.—*Medical Press.*

MISCELLANY.

ANNUAL REPORT OF THE NATIONAL BOARD OF HEALTH.—The report of the Board was presented to Congress February 2. It especially considered the history of Asiatic cholera in this country, and urged the importance of making investigations into the nature of the disease, its mode of communication, methods of introduction, and its clinical history. An appropriation of forty-three thousand dollars was asked for to carry on this work by the National Board, and it was further recommended that half a million dollars be appropriated to assist State and local boards in preventing the introduction and the spread of infectious diseases.

THE HEALTH OF CINCINNATI.—We are indebted to the health-officer of Cincinnati, Mr. C. W. Rowland, for the following figures, which controvert statements which have appeared in our pages and elsewhere as to the bad sanitary condition of the city and the unusual prevalence of epidemic disease. It is positively declared that the sanitary condition of Cincinnati was never better than it has been this winter, and scarlatina and diphtheria have not prevailed epidemically. During November, 1884, the total number of deaths from the former was only ten, and from the latter only six, and both diseases were distributed as to locality. Total deaths from diphtheria in 1884 were seventy-two, from scarlatina sixty-four. The following will give the mortality for the preceding years:

	Diphtheria.	Scarlatina.
1883	78	201
1882	118	336
1881	105	60
1880	103	134
1879	152	546
1878	156	435

These records are open to the public. They show, contrary to the general belief, that the health of the city was unusually good last year, notwithstanding recognized sanitary defects. The total number of deaths in 1884 was 5667; in 1883, 5916; in 1882, 6873; and in 1881, 6101.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 18, 1885, *TO JANUARY* 31, 1885.

PROMOTIONS.

LIEUTENANT-COLONEL JOHN E. SUMMERS, SURGEON.—To be Surgeon, with rank of Colonel. January 9, 1885.

MAJOR JOS. R. SMITH, SURGEON.—To be Surgeon, with rank of Lieutenant-Colonel. January 9, 1885.

CAPTAIN EGON A. KOERPER, ASSISTANT-SURGEON.—To be Surgeon, with rank of Major. January 9, 1885.

APPOINTMENT.

HENRY I. RAYMOND.—To be Assistant-Surgeon, with rank of First-Lieutenant. January 12, 1885.

WEBSTER, WARREN, MAJOR AND SURGEON.—Granted leave of absence for one year, on surgeon's certificate of disability. S. O. 20, A. G. O., January 24, 1885.

TREMAINE, W. S., MAJOR AND SURGEON.—Granted leave of absence for one year, on surgeon's certificate of disability. S. O. 14, A. G. O., January 17, 1885.

MAUS, LOUIS M., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for two months, on surgeon's certificate of disability, with permission to leave the Division of the Missouri. S. O. 16, A. G. O., January 20, 1885.

TAYLOR, B. D., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for one month, to take effect between March 15 and April 1, 1885, with permission to leave Department limits. S. O. 10, Department of Texas, January 26, 1885.

STEPHENSON, WM., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Fort Omaha, Neb., and ordered to Fort Niobrara, Neb., for duty. S. O. 6, Department of the Platte, January 19, 1885.

KEAN, J. R., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Ordered for duty in Department of Missouri. S. O. 23, A. G. O., January 28, 1885.

ORIGINAL LECTURES.

CLINICAL LECTURE ON EMPHYSEMA AND EMPYEMA.

BY FRANCIS DELAFIELD, M.D.,

Professor of Pathology and Practice of Medicine in the College of Physicians and Surgeons, New York.

EMPHYSEMA.

GENTLEMEN,—We have here a man 57 years of age, a painter by occupation, who tells us that he was perfectly well, and accustomed to work regularly at his trade, until last spring. At that time he began to have what he calls rheumatism, affecting especially the muscles of the back. At all events, he had pains affecting the muscles of the back, which have continued and become worse up to the present time. In spite of these pains, however, the man was able to work until about three months ago. He then began to have a cough, accompanied by mucous expectoration. The attacks of coughing are attended with some difficulty in breathing, but, except for the difficulty of breathing during the act of coughing, he says nothing about dyspnœa. He cannot go up-stairs very well, but he does not complain of bad breathing-power. He also has to sit up in bed at night, on account of pains in the back, but not because of trouble in respiration. He has lost some in flesh and strength, and during the three months this cough has existed he has been unable to work.

On examination, we find that he is somewhat emaciated, that his muscles are rather flabby. He is constantly coughing and clearing his throat, as if there were an excess of mucus in the larynx, trachea, and bronchi. On examination of the chest, we obtain the physical signs of emphysema and of bronchitis extending down into the smaller tubes. But you will notice that even after the exertion of taking off his clothing he is not breathing with any great effort. He breathes perfectly quietly, without any undue exertion of the muscles of respiration. His heart is apparently normal.

The diagnosis in this case is, of course, very simple. The man is suffering from emphysema and from chronic bronchitis. But the case is one which brings up very well indeed some points concerning emphysema and bronchitis which I think we are apt to forget.

In the first place, you will notice that, although this man is 57 years of age, yet he is quite positive that this is his first attack of bronchitis. He has not had attacks of bronchitis every winter for a number of years, as you would have thought probable, and which is very often true in patients of his age. According to his account, this winter is the first winter that he has suffered from bronchitis at all; he had always been able to work until three months ago, and has never been confined to bed. The bronchitis which he has now did not apparently begin as an acute attack; or, if it was acute at the commencement, it was unattended with fever. It would seem that it has been either subacute or chronic in character from the first.

Again, you will notice that at the present time the man has well-marked physical signs of emphysema, so well marked that the lesion must have been in existence for a considerable length of time,—much longer, probably, than three months. The ordinary descriptions of emphysema in the text-books, and the ordinary causes which are given for the production of the affection, are, I think, apt to mislead us as regards the real nature of the disease. We get too much in the way of looking at it as if it were a condition due to mechanical causes, as if the dilatation of the air-vesicles were the result of some mechanical interference with the function of respiration. We get in the habit, when we look at a patient suffering from emphysema, of thinking that he must have had a chronic bronchitis for a good while before he had emphysema, and that the emphysema was the result of the chronic bronchitis. We also have the old tradition handed down from one book to another, that persons who play on wind-instruments, or who forcibly exert the lungs in any way, are especially apt to have emphysema, the fact of the matter being that in most cases of emphysema which we see there has been no such cause of the disease at all. But they really present themselves as patients with chronic changes in the lungs occurring as a primary condition, and not as the result of

chronic bronchitis, nor as the result of excessive or forcible expiration or inspiration; not as the result of playing on wind-instruments, but as the result of chronic textural changes in the lungs which resemble very much the chronic textural changes in chronic Bright's disease or in cirrhosis of the liver. The change seems to be more analogous to chronic inflammation than to anything else. When a person is suffering from such changes within the lung, he may or may not develop bronchitis. He may never develop bronchitis; he may die of emphysematous lungs without having had bronchitis at any time. But he is much more likely, some time or other, to have bronchitis.

Still further, you will notice in this man that, although there is well-marked emphysema and bronchitis, yet there is no asthmatic breathing. This man, you would suppose, is in a very favorable way of developing asthmatic breathing, because he has not only emphysema, but he has also chronic bronchitis; yet he has not asthmatic breathing, nor has he any of that constant dyspnœa which we see in so many cases of emphysema. The man breathes imperfectly, it is true, but it does not trouble him; he makes no effort to overcome it. The muscles of respiration move less rather than more than in well persons.

In a man of his age, suffering from emphysema and bronchitis, one of the first things to which we give our attention is an examination of the urine, to learn whether there are any signs of changes in the kidneys. This man's urine contains no albumen, and is of normal specific gravity. If we should find albumen even in small quantity, or low specific gravity of the urine, or an increased amount of the fluid, we should suppose that the man had a chronic interstitial nephritis of the atrophic variety, for this is a very commonly associated condition of emphysema. If the patient do not present any evidence of kidney-trouble, the prognosis is a great deal better.

The next question in this man's case is, what is the best treatment for him? His disease is bad enough to have disabled him from work for three months, and the kind of treatment which he shall receive is a matter of a good deal of importance to him. The man's circumstances are such that it would be impossible for him to go to another climate, and we shall have to do the best we can for him while he remains here. In the first place, it would be a very good thing for him indeed if he could go into a hospital, for this reason: inasmuch as he cannot go away to a different climate, it would be a great deal better for him to stay in the house all the time, not to go out of doors at all; and, that being true, it would be a great deal better for him to remain in a large building, like a hospital, with large rooms, than to remain in a small building with small rooms.

In the second place, we should have to give him certain drugs. He says he has been taking a variety of patent medicines, concerning the nature of which I am ignorant. I should be disposed to begin the treatment with the ordinary mixture of belladonna, ipecac, Dover's powder, and quinine. I should give him the following pill, which I am much in the habit of prescribing:

℞ Ext. belladon., gr. $\frac{1}{40}$;
Pulv. ipecac. comp., gr. $\frac{1}{10}$;
Pulv. ipecac., gr. $\frac{1}{10}$;
Quininæ sulphat., gr. $\frac{1}{2}$. M.

He would take one small pill of this kind every two hours during the day, and through the night when he woke. He might continue to take them for a week. I should expect that at the end of that time his cough would be better, that the expectoration of mucus would be diminished in amount, that his appetite would come back, and he would feel stronger. If this were true, at the end of the week I should give up the use of this remedy altogether, and give the patient one of the mineral acids, very likely combining it with the iodide of potassium, so that he should take, for example, five grains of the iodide of potassium and ten or fifteen drops of dilute nitric acid, with water and glycerin, or with some syrup, three or four times a day, for a considerable length of time.

EMPYEMA.

Some of you will remember having seen this young man once before, although it is a considerable length of time since he was here. He says it was the 10th of October, 1883, that he first came here. He was then suffering from well-marked empyema affecting the left side of the chest. He was sent to Roosevelt Hospital, and there

operated upon for empyema by making two openings into the chest-cavity, one behind and the other in front, passing a drainage-tube through from one opening to the other. After the chest was treated in this way he improved, and finally left the hospital apparently entirely well. His stay in the hospital was from October, 1883, to February, 1884. He remained well until about six weeks ago, when he began to have trouble again; his breathing began to grow short, and his side to pain him. He says a sort of boil formed at the seat of the former opening, and when it was opened he again began to breathe more easily.

The boy, as you see, is not emaciated. The two sides of the chest anteriorly are nearly symmetrical. As he breathes, however, you will observe that the right side moves more markedly than the left, although the latter does move in some degree. You observe where the so-called boil was opened. The resonance is good under the clavicle on both sides of the chest, but on the left as we descend it assumes a tympanitic character, and finally becomes flat. The breathing is normal over the right side of the chest in front. The heart is beating too rapidly, but it is nearly in its normal position, and there are no abnormal sounds. When he was still suffering from empyema the heart was pushed to the right, and the anterior opening which was made in the location which you observe gave no trouble; but as the boy began to grow better, and the heart to resume its normal position, it came in such close proximity to the drainage-tube at the anterior opening that more or less trouble was experienced.

From a posterior view the right side of the chest appears to be considerably larger than the left, and there is a slight curvature of the spine towards the retracted side. Here we observe two scars, one of which was the result of the posterior opening into the chest, and the other, which is lower, arose from an accident which sometimes occurs during this operation. The opening into the pleural cavity was made by degrees, and when the cavity was reached air and pus escaped forcibly, the air having reached the pleural cavity through a perforation by the pus into the lung. Some of the pus and air, instead of escaping directly outward through the opening, infiltrated between the planes of the muscles, and in this way the skin for some little distance became raised from the underlying tissue. The result of this was that for seven weeks there was considerable suppurative inflammation of the connective tissue, which gave no small amount of trouble. The second opening which you see was made to give exit to the pent-up pus between the skin and tissues beneath.

The resonance over the right side of the chest behind is exaggerated, while over the left side there is flatness below and absent respiratory sounds, but above the breathing is fairly good.

What happened in this boy's case is, that after the pus within the pleural cavity had escaped and ceased to form anew, the artificial openings healed up, the heart returned to its normal position, the boy gained in flesh and strength, and the lung expanded to a very considerable degree. But here the reparative process came to a stand-still. The lower lobe of the left lung did not expand, but has remained contracted, non-aerated. The extensive pleuritic adhesions and thickening caused retraction of the chest-walls. If the boy's condition had continued as it was up to six weeks ago, we should have regarded the case as giving a very satisfactory result after the treatment of empyema; but six weeks ago he began to have a suppurative inflammation in the left side of the chest below. It was not a recurrence of the empyema, properly speaking, because there remained no pleural cavity within which pus could form. At that locality there is nothing but collapsed lung, a mass of thickened pleura, and new connective tissue, and it is in this new tissue that the suppurative process has taken place.

What is to be done for the boy evidently is, to treat the local suppuration as we would treat a local suppuration or fistulous tract in any other part of the body. In the first place, the external opening must be made sufficiently large to allow the pus to escape freely, so that it will not accumulate and burrow in different directions. Then the tract of the sinus should be injected with such stimulating substances as would change the character of the tissue lining the suppurative tract and give rise to a granulation-tissue which would cause it to fill up. To enlarge the opening I should be disposed, first, to simply dilate it by means of a sponge or

laminaria tent, rather than proceed at once to make any incision with the knife. I should then explore the tract with the sound, to see how deep it was and to where it leads, and afterwards make the stimulating injections.

There is one feature in the case which I was unwilling to speak about while the boy was present; that is, the urine now contains a little albumen. When he was under treatment before, the urine was normal. A little albumen in the urine in a boy with such a history points very strongly indeed towards the formation of chronic diffuse nephritis, in which there is waxy infiltration of the Malpighian tufts.

ORIGINAL COMMUNICATIONS.

SPASMODIC TABES DORSALIS.*

Read before the Philadelphia County Medical Society, January 28, 1885,

BY JOHN M. KEATING, M.D.

AN interesting article appears in the *Revue mensuelle des Maladies de l'Enfance*, December, 1884, by Dr. d'Heilly, on "Spasmodic Tabes Dorsalis," relating three cases, from which we gather the following valuable points by literal translation:

About 1875, Prof. Charcot separated from the group of chronic myelitis an affection described as *spasmodic* tabes dorsalis, which was about the same time written upon by Erb under the name of spastic paralysis. It is a chronic affection characterized by slow and gradual progression, without doubt of spinal origin, with a paresis of the lower extremities, muscular contraction, and with spasmodic tremors either occurring when the limbs are touched or movements attempted, or else spontaneously. There is also increased tendon reflex.

It is most frequent in adults, but Erb, Seeligmuller (*Progrès Médical*, 1876), d'Espine, and Picot have recorded a number of cases in children. In these cases motion alone is affected; sensibility remains throughout normal. The disease may begin early,—at eight months in one case of the three reported, at two and one-half years in another. Ordinarily it is first found out by the mother, who finds difficulty in flexing the knees or in separating the legs. In well-marked cases the legs are stiffened as the child lies in bed from time to time, especially the feet, which are also turned in (equino-varus). There is contraction of the adductors and extensors of the thighs. At times the rigidity becomes marked; often the knees are held in slight flexion, and it requires some force to move them. On exciting this, the limbs are thrown into a tremor, which may be limited to the feet or may extend to the muscles of the trunk,—in fact, to the whole body. If the child be placed upon its feet by grasping it by the body or arms, the thighs, which are flexed upon the pelvis more or less, will be adducted, the knees touching, the feet will assume a position of forced extension. In attempting to walk, the feet will drag along the ground, stumble over the least obstacle, and constantly interfere with each other. None of the children reported could walk absolutely alone: one could walk a few steps when supported by an object upon which it rested the weight of the body by the arms; the gait was shuffling. The epileptiform tremor of the muscles is at first provoked by standing, and this greatly hinders the walking. In three cases reported, the upper extremities were not involved. This is not absolutely the rule in all cases, but, when the arms are involved, this follows the trouble in the lower limbs, usually at a long interval. In such cases there is a paresis of the muscles without involuntary flexion of the fingers at first, which is intermittent in character and then permanent. The wrist becomes rigid in extension and pronation, so also the elbow, and the arm is hugged to the thorax.

With rigidity comes exaggerated tendon reflex, which according to Charcot precedes contraction, and which persists throughout its course and succeeds it. It is usually very marked in the knees, less so in the feet, and in children is less so than in adults. The symptoms remain confined to the motor tract throughout the disease; the usual symptoms, due to disturbance of sensation, which accompany the different forms of myelitis are absent. There is no rachialgia, no feeling of constriction, no pain; neither are there sensations of cold, nor formications, nor fugitive pains, which, if they existed, would soon be made known by children.

* I would suggest a better name in "Symptomatic Spastic Muscular Contracture."

Cutaneous and deep sensibility are normal; there is neither hyperæsthesia nor anæsthesia. In one of the cases observed there was some well-marked anæsthesia of the lower extremities, but the case was a doubtful one. Sometimes, according to Westphal and Berger, interstitial myelitis may extend itself, involving the posterior tract, and then the symptoms of ataxia complicate the spasmodic contraction. The functions of the sphincters are normal; there is neither retention of urine nor incontinence, which is remarkable for children with disease of the cord.

The muscles of the thigh are not atrophied, and electro-contractility is normal. In one of the cases reported nutrition was excellent, in the other two it was somewhat below par, but this was accounted for by the prolonged enforced rest in bed. The duration of the disease is not limited; complete cure is rare. The symptoms persist indefinitely, despite treatment, without much improvement: if they do become aggravated, the disease is even of itself directly fatal. In children the zymotic diseases, and most frequently tubercular disease, make a fatal termination. It is to be regarded as an infirmity rather than a disease, as it will not of itself prevent the patient reaching adult life. We have written of the affection only in its bearing upon children. In adults it is most common at the age between thirty and fifty, and slightly more frequent in males than in females. The cause is unknown; possibly prolonged exposure to damp cold is the most frequent; in children possibly blows, a fall, or exposure. There is a congenital form, which possibly results from an arrest of or from irregular development in the motor tract, or is traumatic from instrumental or difficult labor. Little records a case such as this, and attributes it to spinal congestion due to asphyxia. Possibly inheritance has its influence. In the case narrated below, the other twin was born with arrested cranial development and lived but a few moments.

The following case serves as an example:

Louis, aged 5 years, entered the hospital (Trousseau) August 30, 1883. The child is a twin; its brother survived but a few moments. The father and mother are in good health; they are not affected with syphilis nor alcoholism. The mother has never miscarried. The child has never walked alone, but since three years old he could stand alone with the aid of a fixed support, and could take a few steps in that way. He began to talk at the age of eighteen months. The disease dates from his eighth month, at which time the mother noticed that she had difficulty in separating the legs of the child; they were straightened and stiffened at times, then became relaxed, and the conditions would again recur, either spontaneously or upon the slightest contact. The arms were in every way normal. About a month after, tremor was noticed when the child was lifted by the arms and held upright on the table. In the following month the contractions increased, and if forcibly overcome would return by themselves at once. Cold douches and faradization brought about some improvement; the permanent crossing of the limbs disappeared, and the intervals existing between the spasmodic contraction of the muscles lengthened.

The condition of the patient at present is as follows. The muscles of the lower extremities are in a state of contraction, the feet extended in equino-varus, and cannot be overcome without considerable force. There is no notable muscular atrophy. When the child is held upright the contraction increases, the inferior extremities are adducted, the feet in equino-varus resting on their metatarsal phalanges. The legs cross, and the foot in advance tends to place itself directly in front of the one supporting the body. The little patient can only take a few steps by supporting himself on his arms. At times the contraction subsides entirely and the limbs become flaccid, but if the limbs are touched, however lightly, or he makes the attempt at movement, the contraction returns. Patellar and plantar reflexes are exaggerated. Faradic contractility is normal. When supported erect, the two limbs take upon themselves epileptiform movements, which can be equally well provoked by seizing roughly the foot in advance. This tremor is more pronounced in the right limb. There has been no pain, either spontaneous or upon pressure. Sensation is normal. The intelligence is somewhat undeveloped. The expression is heavy. Speech normal. The cranium shows faulty development: it is not symmetrical; posteriorly it is flattened. The frontal fossæ, especially the left one, are very prominent. The right occipito-parietal region comes out in bold relief, and the left is correspondingly depressed.

The following typical case, reported by Dr. C. K. Mills in the *New York Medical Record*, September 6, 1879, presented in detail the marked features of the disease, and as I now have the patient under my care, and have been able to study his present condition in contrast to what it was in 1879, I can dwell more at length upon the prognosis.

B. D., æt. 4. Nothing known of the previous history. He has a fair-sized head, but it is flattened a little more than usual from the vertex forward. The fontanels are closed, but the lines of the sutures are projecting and rough. Both pupils are dilated, and according to the nurse they are always in that state. He has left internal strabismus. He has no facial paralysis; he can protrude the tongue without difficulty, and he talks pretty well. He seems to have fair intelligence, but he cries upon the least provocation. His back seems weak, and tends to project backwards as he sits in the chair. He has no spinal curvature. He has good use of his arms, but they show a tendency to flex at the elbows. They frequently get into a semi-flexed position when he is quiet, and sometimes resist extension slightly, but they are not rigid, and he can straighten them himself without special effort. He is unable to stand alone, and if attempts to force him are made he becomes much alarmed; if not held, he falls at once to the floor. Supported by the hand or from behind, he stands in a peculiar position. The legs from the knees upward are slightly drawn together, below the knees they are a little apart. His heels are kept slightly elevated. The thighs are bent on the pelvis at an angle of about 120°, and the legs have about the same inclination as the thighs. The feet turn slightly inward. The flexors and adductors of the thighs and the muscles of the calves feel hard and are in a condition of tonic spasm. He walks in a curious fashion, keeping hold of the hand of the nurse. His legs remain semi-flexed at the knees. He steps on the front part of his feet and toes, the heels never touching the floor. The thigh- and leg-muscles are fully developed, particularly the flexor group. Electro-contractility is generally well retained. Sensibility is good. The limbs are not cold nor changed in color. The joints are free from adhesions. The prepuce is not adherent, and can easily be retracted. When sitting or lying down, his legs can be straightened by the exercise of some force, but they immediately tend to return to their state of abnormal flexion and adduction. Slightly tapping each patella-tendon, the corresponding foot and leg are projected quickly and somewhat forcibly forward. I can produce the same phenomenon by tapping upon the lower part of the tibia. Abruptly forcing the foot into flexion and smartly striking the tendo Achillis, no tremor or oscillation is set up, but the spasm of the flexors and adductors is increased.

Dr. Mills concludes that the disease is one of the motor disorders of the cord of the lateral or antero-lateral columns, but should not be confounded with primary lateral sclerosis, also congenital.

Samuel Gee ("Billroth Hospital Reports," vol. xiii., 1877) writes of spastic paraplegia, and considers the disease as congenital or beginning in infancy. Dr. S. W. Mitchell is quoted by Dr. Mills as having spoken of cases of children with rigidity of the legs from defective cerebral development, and also of cases of spasms of the adductors of the thighs, in which he has had circumcision performed without benefit. Dr. Mills, in this lecture, quotes a case which he saw with Dr. Roland G. Curtin, of this city, where all the symptoms above recorded followed an attack of rheumatism complicated with endocarditis in a girl of 13. She had, in addition, severe pains or aching in the joints or limbs. Under nitrate of silver she rapidly improved, and in two weeks was well.

In the continuation of his interesting article, Dr. d'Heilly (*Revue des Maladies de l'Enfance*, January, 1885) discusses the question as to the cause and seat of this interesting symptom, quoting the researches of Richter and Berger in Germany as showing its dependence in many cases upon a primary sclerosis of the lateral columns. But, again, distinct cerebral symptoms, such as convulsions, in infancy have initiated the attack and the spastic paraplegia following, being in such cases a secondary phenomenon; and in connection with this he quotes Ross (*Spas. Paral. of Infancy, Brain*, October, 1882) as asserting that, although there may be a localized spinal lesion primary, the most usual condition is one of arrest of cerebral development, associated with a bilateral hemiplegia from congenital absence of certain centres; but should this latter explanation be correct, less marked cerebral symptoms should exist than are presented by the cases. Almost all the affections of the cord resulting from pressure or from sclerosis present more or less certain features which show an involvement of the lateral columns; in most of them there is pain or anæsthesia, vesical paralysis or paresis, muscular atrophy or inco-ordination of movement, and the tendency of most of them is to extension.

The ataxia of Friedrich presents many symptoms in accord with this disease. Sensation is normal. The bladder is unaffected, and there is no muscular atrophy. There is muscular inco-ordination and gradual involvement of the arms, and finally speech is affected. Frequent errors

are made in diagnosis in such cases. Even Charcot is reported by d'Heilly as recording a case of supposed spastic paralysis in which the existence of cerebro-spinal sclerosis "en plaques" was found post mortem.

As d'Heilly distinctly emphasizes the fact that "spasmodic tabes dorsalis" never presents any cerebral symptoms, those cases which are recognized as distinctly hemiplegic in character should be eliminated (see excellent paper by Dr. Sarah J. McNutt, *Archives of Pediatrics*, January, 1885), and also double infantile spastic hemiplegia (same author, *Am. Jour. Med. Sci.*, January, 1885). In the latter affection, which more than any other may possibly be confounded with the one in question, Dr. McNutt's exceedingly valuable paper gives us as symptoms "more or less complete hemiplegic motor inability, with contraction and defective development of both bones and muscles," "with or without aphasia, monosyllabic utterances, dysphagia, dyspnœa, and idiocy, the latter being especially characteristic of the double affection."

We have endeavored to epitomize this interesting communication, because we believe these cases to be overlooked in this country or misunderstood. The diagnosis is readily made in marked cases, especially in adults. Doubtless some will read this article and remember cases of their own which had puzzled them. Certainly in the cases referred to by Dr. d'Heilly there was a lesion of a more or less persistent character; but are there not functional derangements, prototypes of the more serious disease, whether disturbances in nutrition or in circulation, which can be influenced by treatment? Can we not have one form depending upon imperfect development of cerebral centres, and another, possibly a difference in degree only, affecting in the same way those of the cord? Cases of functional paraparesis in infancy, with spasmodic adduction, are certainly noted by all who see much of children's practice, and in such cases the muscular wasting, when it does occur, is secondary, owing to want of use.* In our own experience these congenital cases seem to be due to imperfect development, as the intellect shares this condition, though to such a slight extent as only to be noticeable by comparison: the child is said to be backward.

Functional contractions are not infrequent after acute diseases in infancy. A child of my own, at the age of 20 months, had spasmodic closure of the fingers and great rigidity of the wrists immediately following a mild attack of rötheln, which lasted several days (three or four). There was no pain, apparently, and none of the other muscles were affected. When playing, she lifted her toys with the back of her wrists. Nutrition was perfect, the functions normal. In this case relaxation would come on at times, but the slightest touch or effort on her own part would bring about violent contractions. There was relaxation during sleep. I noted this same condition following measles, in an infant, which involved the muscles of both arms and legs, the extensors of the legs and the flexors of the arms, with contraction of the toes and fingers. There was pneumonia in this case, and the temperature ran high. The little patient gradually improved; in fact, in both these cases the improvement was very gradual. Large doses of bromide of potassium, hot baths and friction, with tonics, were used in the first case, and in the latter quinine and poultices in addition. Possibly these cases may be called hysterical. The lesion is evidently an irritative one, but exactly why it should be limited to certain cord-centres and be painless is an interesting problem.

But in such cases as reported by Dr. d'Heilly, when changes have probably taken place of a definite character, and especially if they occur in children but a few months old, our only chance for treatment points to alteratives, tonics, and encouraging nutrition.

Like all other symptoms, contraction may represent in infancy and childhood, as well as in adults, simple irritation (hysterical, possibly), and every grade to advanced disease. I think chorea may be classed in this category also.

As for the treatment of well-marked cases of spasmodic contraction, there seems but little hope of doing good. The disease, whatever its lesion may be, is limited, is never fatal, and after reaching a stage about as advanced as the boy B. D., quoted from Dr. Mills's report, somewhat improves. This boy can now

* This I believe should not be confounded with the so-called idiopathic contracture of infancy, which is the result of irritation and is painful and acute in character.

take a few steps by himself before the muscular spasm upsets him; he is in excellent health, well nourished, muscles firm, and never complains. But in this case the lesion certainly seems to be a bilateral central one. If we are able to recognize the features of the disease of the spinal types in its incipiency, I believe much could be accomplished; and it is for this reason that I bring this matter before you this evening.

All causes of irritation should be removed. If they are males, possibly preputial adhesions are present: they should be broken up or circumcision performed. In my opinion the latter is a most important operation, not so much from the relief to the phimosis, which could be, in many cases, equally well accomplished by stretching (Willard), but owing to the direct results upon the nutrition of the spinal centres, which section of the peripheral terminations of the nerves in the prepuce may bring about, acting as will the actual cautery or blisters in other neuroses. In females I would give warm baths, alternating with cold sponging, especially to the spine, and full doses of bromide of potassium. In incipient cases the bromides are of great importance, with stimulating frictions to the spine, using either mustard poultices, or liniments of oil of amber or croton oil, or possibly dry-cupping. Fresh air and proper diet are, of course, understood; in the latter, milk should always form the principal part, and eggs also, in preference to animal-broths. As regards medication, I would insist upon an emulsion of cod-liver oil, either with liq. acid. phos. comp. (Pepper), or lacto-phosphate of lime. Arsenic is certainly of great value in these cases. As to quinia and strychnia, I feel doubtful as to their use, even in very small so-called tonic doses; for although the condition is possibly an evidence of anæmia, as are chorea and some mild forms of epilepsy, I would prefer to rely on food, iron, arsenic, and fresh air.

In more pronounced cases, when we have decided evidences of "spasmodic tabes dorsalis," and treatment has been of little avail, we might use the bichloride of mercury, in small and frequent doses ($\frac{1}{150}$ of a grain), three times daily; or, if we suspect sclerosis, the chloride of gold and sodium. But I think that the best results are obtained with the nitrate of silver; in it I would place most reliance. Erb is reported as having cured a case with the continued current. Charcot failed with electricity, hydropathy, and cauterization.

HYDROCHLORATE OF COCAINE IN PURPURA HÆMORRHAGICA.

BY WILLIAM F. WAUGH, A.M., M.D.,
Professor of the Practice of Medicine, etc., Medico-Chirurgical College.

A LADY aged 27 years had had several profuse hemorrhages within a period of four months. Her color was still good; her health apparently unimpaired; but her blood had become deficient in coagulability, so that a slight prick on the finger occasioned hemorrhage which was only checked with difficulty.

She had no previous history of unusual hemorrhages. Her mother was subject to epistaxis which on more than one occasion necessitated the attendance of a physician, and at one time continued nearly a week.

Since the middle of December the lady had several premonitory symptoms. On the 18th of December, after unusual fatigue, she fainted. After this date several uterine hemorrhages occurred of small amount. On the 1st of January she complained of a sense of fulness in the head, as if her nose were about to bleed. That evening she took six grains of quinine. Later the same evening she felt something like a fragment of food between two of her teeth, and endeavored to remove it by drawing the edge of a handkerchief between them. At once the gums commenced to bleed from where the handkerchief had been used, and, later, from a number of other places. On the lips, tongue, inside of the cheeks, gums, and roof of the mouth appeared a number of purple spots from the size of a pin-head to that of a silver half-dime. A blue spot the size of a half-dollar appeared on the right thigh, and another on the right shoulder. On the face, neck, chest, and limbs, the spots were smaller and bright red. Slight discharges of blood took place from the womb. The stools were tarry. The face was pale, the skin cool, the pulse weak and compressible. She complained of alternating flushes and chills, and of vertigo whenever she attempted to rise from the recumbent posture. The elbows and knees ached as if they had been bruised.

From this time until the evening of the

3d, I was engaged in trying the various styptics to check the blood which oozed from the gums. Alum, tannin, phénol, phytolacca, and Monsel's solution were used with no appreciable effect. The only local remedy which checked the hemorrhage was ice; and of this the effect was but momentary. Internally, phytolacca, ergot, digitalis, and hydrochloric acid were given. After forty hours the hemorrhage was still increasing.

In this predicament I remembered having read in one of the recent reports upon hydrochlorate of cocaine, that after its use there was less hemorrhage than in operations conducted without it.

I procured a little of a four-per-cent. solution of the drug, and applied it twice to the bleeding gums, and to a spot on the under lip where the blood was just beginning to gush out. The next time I saw my patient, in about three hours, I found the hemorrhage had entirely ceased, except at one point. Here the gum was covered with a clot of blood. I removed this and applied the cocaine solution directly to the bleeding surface, and in five minutes the hemorrhage ceased, and did not return.

On January 5, I removed an eye-tooth, with a very long root, from the mouth of a lady in her eightieth year. She dreaded the operation greatly, as she had had serious hemorrhage from the same cause not long before. When the tooth was extracted the blood began to flow freely; but simply pressing a bit of cotton saturated with cocaine solution into the cavity stopped the hemorrhage at once.

A few days later a lady came to me with a simple inflammatory swelling of the upper lip. I applied the cocaine solution, but in spite of it the inflammation went on to suppuration. This but seldom happens when such cases are treated with continuous applications of hot-water cloths. From these cases I would infer that cocaine has valuable powers in checking capillary hemorrhage of a passive kind, but none whatever in controlling crescent inflammation.

Its physiological action, as determined by applying the solution to the web of a frog's foot, is to cause contraction of the blood-vessels, followed by dilatation. This secondary dilatation, however, did not occur in the case of purpura.

I wish to add one more to the uses of this drug as a local anæsthetic. The removal of hairs from the lips and chins of ladies, by electrolysis, is in some cases exceedingly painful. To many the operation is practically painless. Others bear the pain with patience for the sake of getting rid of the ugly deformity. But to anæmic, highly neuralgic persons the pain is sufficient to deter them from the operation. In several cases of this kind I have found that applications of the four-per-cent. solution to the skin, repeated every ten minutes, render the process absolutely free from pain.

1521 Arch Street, January 20, 1885.

STATISTICS OF NEPHRECTOMY.

BY CHARLES BAUM, M.D.

VERY general interest has recently been aroused by the surgical operations upon the kidney. Among these, incision into a kidney, or *nephrotomy*, can probably claim the greatest antiquity, being mentioned by the early writers on medicine. The removal of a calculus from a kidney by enlarging an existing sinus is also of ancient practice; but the operation of the removal of the renal calculus early in its formation and before the enclosing structures have become implicated was performed first by Henry Morris, of London, at so recent a date as 1880. As "floating kidney" has been observed in quite a number of persons, being more frequent in women, surgeons have attempted to remedy the difficulty permanently by suturing the organ to an incision in the parietes. This procedure, called *nephrorrhaphy*, promises well, the results thus far having been encouraging.

Vivisections have repeatedly and fully shown that animals can live after the extirpation of one kidney, and many examples of congenital absence of a kidney have also been found in the post-mortem room. Having these facts in mind, the late Gustav Simon, of Heidelberg, projected and successfully performed the first *intentional* extirpation of the entire kidney, or *nephrectomy*, operating by the lumbar incision. Since his successful case, many operations have been recorded, one hundred of which have been tabulated by Dr. Robert P. Harris in the *American Journal of the Medical Sciences* for July, 1882. The annexed table comprises seventy-two additional cases:

No.	Reference.	Date of Operation.	Operator.	Sex and Age.	Incision (A. Abdominal; L. Lumbar).	Diseased Condition.	Recovered; Died.	Cause of Death.

Of these 72 cases, 32 recovered, 36 died, and in 2 the result is not stated.

Of 40 females, 17 recovered, 21 died, and 2 not stated. Of 11 males, 7 recovered and 4 died. Of 7 children under 12 years old, 2 recovered and 5 died.

The site for operation was stated in 62 cases, of which 44 were by abdominal section, with 19 recoveries and 25 deaths, and 18 by lumbar incision, with 11 recoveries and 7 deaths.

The conditions demanding the operation were the following: Abscess, 2 died; calculous pyelitis, 2, 1 died; calculous pyonephrosis, 1 died; calculus, 2 cured; carcinoma, 6 died; cystic disease, 4, 1 died and 1 not stated; fibroma, 1 died; fibro-cystic disease, 1 cured; floating kidney, 3, 2 died; hydronephrosis, 3, 2 died; lipoma, 1 died; misplaced kidney, 1 died; misplaced and single kidney, 1 died; myxo-sarcoma, 2 cured; papilloma, 1 cured; pyelonephritis, 1 died; pyonephrosis, 8, 6 died; sarcoma, 4 died; traumatic rupture, 2, 1 died; tubercular disease, 4, 2 died and 1 not stated; tumor of capsule, 2 cured; tumor (?), 1 cured; urinary fistula, 4, 1 died; and wound during ovariotomy, 1 cured.

The chief causes of death were collapse, 5; peritonitis, 4; peritonitis (complicated), 3; shock, 4; exhaustion, 3; hemorrhage, 2; and syncope, 2; while anuria was a factor in 3 cases, and perhaps carbolic-acid poisoning in 1 case.

Actuated by pain, Lane's patient declared she attempted to excise the swelling, and to corroborate the statement directed attention to a cicatrix which was observed upon her abdomen. In attempting to extirpate a renal tumor by abdominal section, Tait failed on account of the great matting of the intestines; nevertheless, the tumor decreased in size and the patient improved. However, as her symptoms reappeared, he removed it three and a half months later by the lumbar incision. Polk removed the misplaced left kidney from a young woman, 19 years old, in whom there was congenital absence of the right kidney and no trace of the corresponding ureter. In this girl the breasts were large, but the labia minora rudimentary, and there was absence of the vagina and uterus, while the ovaries appeared normal, but were misplaced. After the operation frequent emesis and dry skin occurred, but sweating was induced by pilocarpine; finally, after eleven days and one hour of moderate suffering, convulsions and coma produced death.

The kidney which Morris extirpated for calculus was normal in structure, but "harder and firmer" than usual. Two attempts, both digital and with needles, had failed to detect the stone.

The object of this paper has been to present a number of cases of nephrectomy for the study of those who may not have had the opportunity to collect them. For various reasons, it was found impossible to make a complete list, therefore the table does not comprise all the cases operated upon since the paper of Dr. Harris appeared. Much kind assistance has been received from Professors Ashhurst and Gross, of this city, and Professor Weir, of New York.

630 North Broad Street.

REPORT ON THE PROGRESS OF OTOLOGY.

BY CHARLES H. BURNETT, M.D.,
Philadelphia.

(Continued from page 348.)

TREPHINING IN MASTOID AND TYMPANIC DISEASE.

AN article with this title appeared in the October number of the *Dublin Journal of Med. Sciences*, from the pen of W. I. Wheeler, F.R.C.S.I., M.D., and is presented to American readers in the *New York Med. Abstract*, November, 1884. We feel called upon to notice it here, and to criticise unfavorably the views set forth therein.

First, the statement that the membrana flaccida is the most frequent seat of perforation in the membrana tympani is just the reverse of the fact: it is a most unusual seat of perforation, as every otologist knows. It is but fair to state that the author, Dr. Wheeler, does not profess to be an aurist, and hence his inaccuracy on this score is somewhat excusable. Secondly, in the first case, notes of which he gives, in which he trephined the mastoid, there is no good evidence in the history of the case that the perforation was demanded. No pus escaped from the opening for twenty-three hours after the operation. The secretion was undoubtedly then the result of the trepanation. Fortunately, the man recovered, although the dura mater had been exposed by the operation. In

the other two operations there seem to have been symptoms warranting the trephining of the mastoid, but in both of these cases the dura mater was exposed intentionally, as it is stated. Both, however, recovered. This intentional exposure of the dura mater in the operation for trephining the mastoid seems very singular, as aural surgeons endeavor to avoid this complication in operating on the mastoid. And hence we consider the advice and directions given by the author in concluding his article as pre-eminently unworthy of following. In fact, the use of a trephine of the size he seems to have used, judging from the pictures of the button removed from the mastoid cortex, which accompany his article, is to be deprecated. (The diameter seems to have varied from one-half to three-quarters of an inch.) When the mastoid cortex is to be perforated, a small drill or a gouge is used by aurists who have performed this operation the most frequently and the most successfully. After stating where to place this broad trephine, (which is too comprehensive to be safe,) the author concludes his article with these to us seemingly remarkable words: "By adopting this course there will be no danger of wounding the lateral sinus; the tympanum and mastoid cells will be opened, giving full exit for discharge; the *dura mater will be exposed, and should pus exist between it and the cranium there will be ample freedom for its escape.*" (The italics are the reporter's.) This seems to be a strange mixture of general and special surgery, and a very poor exemplification of the latter. To trephine or perforate the mastoid cortex for pus within the mastoid cavity is often demanded, and the indications for it and the method of their fulfilment are now fully established, but a combination of them with laying bare the dura mater is nowhere set forth as desirable. To trephine the skull wall and expose the dura mater has also its indications, but does not enter into mastoid operations as a rule, and hence we have felt that the statements and doctrines contained in the strangely conceived paper under criticism should not go unchallenged by otologists.

PEROXIDE OF HYDROGEN IN MASTOID ABSCESSES.

Dr. A. E. Prince, of Jacksonville, Illinois (*St. Louis Med. and Surg. Journal*, March, 1884), calls attention to the merits of peroxide of hydrogen as a cleansing agent in suppurating cavities.

Peroxide of hydrogen is physically like water, transparent, colorless, limpid, odorless, and tasteless, with sp. gr. 1452, and remains liquid at zero. Chemically, it is one molecule of water connected by a feeble bond to an atom of oxygen, and is obtained by the action of hydrochloric acid on peroxide of barium: $BaO_2 + 2HCl = BaCl_2 + H_2O_2$. Its importance as a therapeutic agent is due to its instability. "In the presence of a variety of substances, as gold, silver, and platinum, fibrin and cellular tissue, it is decomposed into water and oxygen, becoming at the same time a powerful oxidizer."

The fact most interesting to the surgeon is the remarkable power possessed by pus to decompose this agent with liberation of nascent oxygen, which directly adheres to and attacks all the adjacent tissue for which it has an affinity, and it thus becomes a powerful destroyer of bacteria. It is claimed for it that, though inferior to iodoform as an antiseptic, it has the inestimable quality, like it, of producing little or no irritation when used about tender organs. Upon coming into contact with pus in a fetid cavity the liberated gas permeates it, and by the continued evolution of gas the cavity may be emptied of its contents, which boil out at a fistulous opening or any other vent so thoroughly mixed as to appear like froth or foam. Some ascribe to this cleansing character rather than to its antiseptic power its beneficial effects in the treatment of suppurating cavities.

Dr. Prince reports the case of Julia, 8 months old, suffering from suppuration of the middle ear following scarlatina, and after ten weeks supervention of mastoid inflammation and symptoms of general septic poisoning. When examined by him, the child had continued fever and loss of appetite. An examination of the ear revealed destruction of the drum-membrane, exceedingly offensive pus, granulations in the tympanic cavity, with swelling, redness, and heat over the mastoid, or rather over the mastoid region, because a child of this age has no true mastoid cavity any more than it has an osseous auditory canal, as these both have to grow for several years before they can be said to fully exist. A drill was passed through

the outer wall of the mastoid directly into the cavity of the tympanum, and a flexible lead wire passed through from this opening into the tympanic cavity and out through the auditory canal. All injections passed through the drainage-course thus made failed to relieve the patient. Finally a hypodermic syringeful of the peroxide of hydrogen was injected into the drainage-tract from the mastoid opening, the finger being held over the auditory meatus. The liberated oxygen seemed to penetrate the recesses of the mastoid-tympanic cavity, and finally boiled out of the external openings. By repeated injections, so long as any pus remains in a cavity the oxygen will continue to be liberated. Hence when gas is no longer evolved an evidence exists that the cavity is empty and its surfaces free from pus. The constitutional symptoms in the case alluded to began at once to improve, and the case was rapidly cured by the further use of boric acid insufflations alternated with alcohol instillations.

ON THE NECESSITY OF PROVIDING FOR THE BETTER EDUCATION OF CHILDREN WITH DEFECTIVE HEARING IN THE PUBLIC SCHOOLS.

Dr. Samuel Sexton, of New York, has written a paper with the above title (*New York Med. Record*, December 20, 1884), its object being to enlist an interest in the public school system in so far as concerns the needs of the pupils whose disabilities of hearing prevent them from advancing with scholars with good hearing, since it is believed by the author, in common with many others, "that this matter does not receive the attention which its importance demands."

The varieties of deaf children who are believed to be greatly neglected in regard to their education are the following: 1. Children with defective hearing in one or both ears and requiring close proximity and distinct utterance when taught. Of these deafness in both ears requires seating on a front row of benches, but where only one ear is affected the normal ear must be towards the teacher's desk. 2. Children very deaf, who cannot distinguish ordinary conversation in either ear when more than a few inches from the speaker, or unless the conversation-tube or acoustic fan or other aid to hearing be employed. 3. The totally deaf, in whom the auditory apparatus of the middle ear cannot be made available. This class admits of division into two subdivisions,—viz., (*a*) those having learned to talk previous to losing their hearing, and (*b*) those born too deaf to ever have naturally acquired speech, commonly known as congenital deaf-mutes.

Deafness in the schools is then considered from a physician's point of view, as it is believed that the extent and importance of the subject may be more fully realized in this way than in any other, "since where professional advice is required, opportunity is allowed for thorough examination of the hearing organs, both as regards their physical condition and acoustic functions."

Dr. Sexton's experience has led him to the conclusion that "among school-children of the poorer class great injustice is being done in permitting children to struggle for an education under the disadvantages arising from deafness without the aid of methods which experience has shown to be advantageous in such cases."

In New York City it has been shown that some children continue on at school for years while scarcely able to hear, while there are many others who hear very badly. In disregarding this matter deaf children are placed at a serious disadvantage, and time is wasted in futile attempts at instructing them, which proves a hinderance to others who can hear. Great injustice may be done to children with defective hearing, even when they have made great efforts both at school and at home to prepare themselves for promotion, if they are put back at examination, as has resulted because the principal, being unaware of the child's aural defects, has not given his questions distinctly enough for the child to hear them. Deaf children, from neglect to classify them, may be seated too far away from the teacher's desk to hear his voice, and in consequence of inability to hear are often punished for inattention and dulness. In consequence of this misunderstanding many pupils leave the school and lose advantages they cannot afford to dispense with. It is not recommended that the partially deaf should be entirely separated from the hearing pupils, yet it is advisable that pupils should be examined in regard to their hearing, and "that those found to be defective should be given every possible advantage, both in respect to seating and to distinctness of voice in teaching." The very deaf should have some instruction apart from others,

since they cannot hear in some instances words shouted into their ears. An examination of the hearing of five hundred and seventy-five school-children made in 1881 by Dr. Sexton showed that fully thirteen per cent. of the whole number had greater or less hardness of hearing in one or both ears, and that only three per cent. of them were themselves aware of the defect, and only one was thus known to the teachers.

Careful estimates have been made, showing that no more than five per cent. of the entire population of the United States have normal hearing, "but this of course does not show the number of persons defective enough to exclude them from the benefits of the ordinary common-school curriculum. The tenth census computes that there are about thirty-five thousand deaf-mutes in the United States, or one in every fifteen hundred. One-half of these are illiterate." Dr. Sexton carefully estimates the number of totally deaf children unprovided with school advantages in New York City at five hundred. He further makes the important deduction for New York City that, "out of about one hundred and forty thousand pupils in attendance at the public schools at the present time, some fourteen thousand of them would be the better for classification in respect to seating and instruction at short range, or by means of some aid to hearing, and he claims that this avenue to illiteracy — viz., defective hearing — demands attention in a large population where vagrancy and kindred evils are attracting so much attention from the vastness of their proportions.

The author then draws attention to the fact that a very considerable number of deaf-mutes may be more advantageously provided for in the public day-schools than otherwise, as in many cases parents do not like to relinquish their children for purposes of educating them in boarding-schools for the deaf-mute, as they must do if they are to be sent to such institutions as at present organized, with but few exceptions. Day-schools for deaf-mutes have been increasing in number since 1869, with the foundation of the Horace Mann Day-School in Boston. The Oral Branch of the Pennsylvania Institution, a day-school for the very deaf and deaf-mutes, was established in 1881, and the newest ones are the Scranton Oral School, 1883, and A. Graham Bell's School, Washington, D.C., 1883. In such schools as these very considerable numbers who are at present being educated as deaf-mutes could be cared for along with the very deaf who are at present unprovided for, since they both require similar methods of treatment. Furthermore, the education of totally deaf and very deaf children should be undertaken at the age of five or six years, much earlier than is feasible or is done in Deaf and Dumb Institutions. Children who have lost their hearing soon after learning to talk forget this acquisition unless kept in practice. Early education in oral schools for the deaf would enable them to retain speech, and if the congenital deaf-mute is placed in the same school at the same early age, it is not obliged to lose valuable time at an impressible age, as it does if it waits to be admitted to ordinary schools for deaf-mutes requiring a greater age for admission. Children of such tender age must be accommodated with day-schools near home, an entirely practicable matter not only in cities and towns, but in sparsely-settled districts. Other points connected with this important topic will be considered in the next Report on Otology.

"LAWN TENNIS" BACK.

BY CHARLES McINTIRE, JR., M.D., F.A.A.M.,

Medical Director, Gymnasium, Lafayette College.

SO much is written about the "tennis arm" and "tennis leg" that I may be pardoned for coining the caption to this article, although the application of the term is not strictly accurate.

While making the preliminary physical examination and measurements of the class of '88, Lafayette, last fall, I found one of the students showing such a marked difference in the development of the muscles of the right side, more especially those of the back, that I was led to inquire his favorite pastime, and found that he was passionately fond of lawn-tennis, so much so that the previous summer had almost been entirely devoted to that sport.

The accompanying photograph* shows much more clearly the marked development on the right side and the want of it on the left than any description, while the

* In the photograph accompanying the communication this want of symmetry is very evident.—ED. P. M. T.

measurements of the upper extremities also show the same disproportion. He is 17½ years old, is 1716 millimetres tall, and weighs 50.25 kilogrammes. The upper-extremity measurements are as follows, in millimetres:

	Right.	Left.
Shoulder . . .	399	373
Arm, biceps contracted	253	232
" " at rest .	230	210
Forearm, muscles at rest	235	209

The lesson to be learned from the case is an easy one. In our anxiety to provide exercise for the young, we must not forget that physical development, while depending upon exercise, is not synonymous with it, and if the exercise is carried on by one set of muscles chiefly, while we may obtain the desired benefits to the circulatory, digestive, and nervous systems, we will also obtain an asymmetrical body. Of course a single case does not afford any foundation for an argument *pro* or *con* as to the fitness of any game as an exercise, and doubtless the many are greatly benefited by the use of the racket; but a caution as to the excessive use of the one arm and an exhortation to become ambidextrous would be a fairly-deduced sermon from such a text.

In this individual case special exercise has been given in the gymnasium, having for its object the development of the muscles of the left side, and we hope before he is graduated to have him symmetrically and well developed.

The need of giving more thought to the matter of physical development by the physician, as the health-conservator of the nation, is emphasized by the examinations now commonly made in gymnasiums. A little observation and a few words of kindly advice would frequently prevent the formation of an irregular development which in after-life is difficult, if not almost impossible, to correct.

Congenital Malformation of Large Intestine.—The *Lancet* for January 31 contains a clinical report of the case of a child, two days old, operated upon at the Sheffield General Infirmary by Mr. Atkin, for imperforate anus. The operation of Littré was performed, but the large intestine could not be found. At the autopsy it was found that the whole colon and rectum were rudimentary and apparently solid, although a little meconium could be pressed through it by exercising considerable force. The anus was imperforate.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY HOSPITAL.

CLINIC OF JOHN ASHHURST, Jr., M.D.,

Professor of Clinical Surgery in the University of Pennsylvania.

Reported by Louis J. Lautenbach, M.D.

DRY SYNOVITIS, WITH INTRA-ARTICULAR ADHESIONS OF SHOULDER-JOINT.

THE first patient whom I have to show you to-day is a little girl who has received a slight injury of the right shoulder, which has been followed by pain and some limitation of the motions of the limb. Taking the arm in my hand, I find a decided crackling on movement. This is what is known as false crepitus: it is a dry crackling, which is rather felt than heard, and which is produced by the rubbing together of roughened surfaces which are ordinarily smooth. It may be intra-articular, from the friction of the head of the bone in the glenoid cavity, or it may be developed in bursæ, or in the synovial sheaths of tendons. It may occur with arthritis, and also with periarthritis. It may be connected, that is, not only with disease of the joint, but also with disease of the tissues around the joint. Between these two sources of origin it is often very difficult to make the diagnosis, and it is frequently only by the most careful examination that the intra-articular or extra-articular nature of the disease can be determined.

My first impression on looking at this patient was that the stiffness and crackling on motion were periarthritic, but more careful examination while the child is etherized shows that the tissues surrounding the joint are soft and healthy. The disease is not arthritis, but a synovial affection which is described by Mr. Barwell as dry synovitis. There is a change in the synovial surfaces of the joint, causing a dry crackling when the parts are rubbed together.

Periarthritis is a condition of considerable importance as being frequently met with and often not recognized. It has been particularly studied by French surgeons, especially by Gosselin and Duplay, who have furnished excellent accounts of the affection as observed in the tissues around the shoulder and the knee. One lesion, which is sometimes met with in this disease as located in the shoulder, has been

described for many years and has been misunderstood. I refer to the lesion described as dislocation of the tendon of the long head of the biceps muscle. There is reason to believe that in most, if not in all, of the cases in which the tendon has been found displaced from its groove, this condition has been not the result of injury, but of chronic inflammatory changes due either to rheumatoid arthritis, or, which I think is more often the case, to the extra-articular affection which we know as periarthritis.

Here there are no evidences of a change outside of the joint. I think that this is a case of dry synovitis, with a certain amount of intra-articular adhesion. I intend to move the arm forcibly so as to break up the adhesions, and then to apply equal parts of mercurial and belladonna ointment, and fix the limb for forty-eight hours to prevent any inflammatory reaction. At the end of that time the movements may be repeated, and, if the child's parents can be induced to co-operate with the surgeon in maintaining mobility, complete restoration of function may be expected. The results of treatment in these cases, however, depend almost entirely upon the care which is exercised by the parents or friends of the patient.

In trying to break up adhesions in the shoulder-joint you must fix the scapula, as otherwise it will move with the arm; then with a series of short but rapid jerks (for you want to break and not to stretch the adhesions) you should move the limb in various directions, first by flexion, then by extension, and finally by rotation and circumduction. Doing this while my assistant fixes the scapula, I can feel the adhesions giving way. By what may be called gentle violence you can thus accomplish your purpose; but of course you must not use too strenuous efforts, as by so doing you might break the bone or perhaps lacerate the great vessels or nerves in the axilla. These manipulations may be repeated after forty-eight hours, provided that the joint does not feel hotter than the surrounding parts; but if its temperature is still elevated at the end of that time, the interval must be made longer.

CASE OF SYPHILITIC OSTEITIS AND NECROSIS OF ULNA.

This young woman, with a syphilitic gumma upon her forearm, has also some sinuses around the elbow-joint evidently leading to disease of the olecranon.

Here we have dead bone present, and the process of separation is so slow in syphilitic necrosis that we are justified in interfering when we would not be so in a case of ordinary necrosis. The rule in ordinary cases of necrosis is not to operate until the dead bone has become loose, but frank sequestra do not form in syphilitic necrosis. I will make an incision down to the bone, and will endeavor to scrape away the diseased surface.

I do not expect to find here any well-marked line of demarcation between the living and dead bone. If I were to remove all the bone which did not appear entirely healthy, I might perforate the olecranon and thus open the joint, a complication which, although not very dangerous, yet should be avoided if possible.

I make a longitudinal incision, push back the tissues, and endeavor to remove the diseased bone without going further than is necessary. I must not get too near the tip of the olecranon, as I do not wish to interfere with the attachment of the triceps muscle. With the thumb-gouge I can scrape away the dead bone. Probably the surface only is necrosed, and I can thus get a sufficiently healthy layer of bone to allow granulations to form and the parts to heal. There are no sequestra here to come out. The operation is rather like one for caries.

We will over the wound use the ordinary dressing of oiled lint, oiled silk, and bandage. On the gummatous tumor we will use mercury and belladonna ointment, and will get by this means both the anodyne effect of the belladonna and the absorbent effect of the mercury. We will put the patient under the use of iodide potassium continued for a long while. Under this treatment she will no doubt improve, and probably the ulceration will heal. I must say, however, that operations for syphilitic necrosis are not very satisfactory, and that we may not succeed in obtaining a cure without further interference.

APOMORPHINE IN ASTHMA.—Dr. Weber, of Darmstadt, has used apomorphine, in doses of one-twelfth of a grain three times a day, in chronic asthma, with success. One patient was entirely relieved who had been a sufferer for thirty years.—*Chicago Medical Journal.*

TRANSLATIONS.

Carbolic-Acid Inhalations in the Treatment of Diphtheria.—Dr. Ludwig Stumpf, of Munich, contributes a very valuable paper on the treatment of diphtheria to the December (1884) number of the *Deutsches Archiv für Klinische Medicin*. He concludes that the diphtheria of the throat, nose, vagina, and mucous membrane of all the air-passages is in the first place a local disease. Commencing as a purely local affection, it will progressively develop into a general systemic infection of the whole body. From the local nature of the infection, topical treatment of the disease is justifiable and in accordance with the opinions commonly held at present. If a local disinfection is accomplished soon enough in accordance with the Listerian principle, all can be accomplished which is needed. The best treatment is the inhalation-treatment. Up to the present time we have no remedy against the general systemic affection. The object of the physician should be to grasp the local primary disorder as speedily as possible, before the general system has been invaded. The importance of this primary treatment, therefore, cannot be overestimated. By neglecting the proper local treatment the general infection of the body will result, and when this takes place our medical efforts are often unavailing. Such cases are generally fatal.

The value of a remedy in the treatment of diphtheria is to be estimated by its disinfecting properties, or, in other words, its bactericide action. The best means of combating the disease is the application of medicated vapor by inhalation, selecting those remedies which possess the greatest antiseptic properties with the least injury to the patient. Helfer was the first to use the atomized solution of carbolic acid in proportions of 1 : 50 and 1 : 30, and has published his excellent results in the treatment of sixteen cases by this method. Rauchfuss considers this application too strong; but Stumpf, on the contrary, believes that these remedies have been disappointing to many experimenters because they were too weak! The full antiseptic and parasitic action of the carbolic acid is only developed by a five-per-cent. solution. Stumpf uses a solution of this strength from five to seven minutes by steam atomizer every hour. No disinfecting remedy is so powerful in its operations and at the same time so harmless to the patient as carbolic acid. Its action requires only to be seen to be appreciated, as demonstrated in the prompt cleansing action of the mouth and throat. After a few inhalations of a five-per-cent. solution the disagreeable odor of the breath disappears, and the loosening of the discolored membrane goes on rapidly without any odor. This treatment of the membrane by carbolic acid is painless, and so much the less painless in proportion with the amount of the deposit. If properly managed, the destruction of the healthy mucous membrane by this treatment is not to be apprehended. By the admixture of the steam in this treatment, the five-per-cent. solution is really reduced to three or even two and a half per cent. by the time it reaches the throat. [During its use attention should be given to examination of the urine to detect any evidence of toxic action.] P.

Quinine in Typhoid Fever.—Dr. Goldscheider, in the December (1884) *Deutsches Archiv für Klinische Medicin*, in an article upon the Action of Quinine in Typhoid Fever, says that undoubtedly quinine has an effect upon the "typhus curve" which is usually exhibited after each dose. This effect is neither specific nor absolute, but it requires certain conditions. It is dependent upon the quality of the fever. It does not in general break the typhoid fever, neither does it shorten it, but operates in diminishing the pyrexia. It supports the remitting tendency, and it has a certain influence upon its exacerbation. In consequence of this, like every remedy, it has an uncertainty in its action, because its effect is dependent upon unknown conditions. In severe forms of the disease the therapeutic effect is in most cases unsatisfactory, particularly in the first half of the disease; during the second half it operates better. It is in the latter stage especially that its antipyretic effects are best observed. The general condition and the pulse also will be improved by its employment at this stage of the disease. P.

Eczema due to Iodoform.—In the *Deutsche Med. Wochenschrift* for July 24, 1884, Dr. A. Neisser cites several cases in which iodoform applications caused an obstinate eczematous eruption. Possibly the drug was adulterated.

EDITORIAL.

OVERWORK AND NEURASTHENIA.

IN the Toner Lecture delivered last year by Dr. Chas. K. Mills, of this city, the subject of Mental Overwork and Premature Disease among Public and Professional Men was very appropriately selected, at the suggestion of the founder of the lectures, and to its consideration the lecturer brought the results of considerable clinical observation and original investigation. His statistical studies of men in political and official life, and also of professional men considered as a separate class, favor the views already generally held,—that intellectual work does not of itself injure health or shorten life, but mental overwork, particularly when associated with emotional strain, is a frequent cause of nervous break-down and premature disease. He considers that the longevity of men in the higher walks of public life is less in this country, generally speaking, than in England, basing his opinion upon the average age at death of public men. It does not appear, however, that sufficient importance is given to the fact that in Great Britain the responsibilities of political life are, as the rule, begun later, while the time actually devoted to the duties of public life is less and the attendant mental strain much lighter, than here.

The lecturer cites, among the special causes of premature disease in public life, the onerous and perplexing duties required by service on committees, the uncertainties and disappointments of this life, and the strain to which candidates are subjected during political campaigns; with lack of recreation, and the social excesses and abuses at the national capital.

Among physicians, lawyers, and journalists the performance of brain-work under pressure for time, and under bad hygienic conditions, is a common cause of ill health. Defective education and pecuniary embarrassment are also special causes of nervous break-down and premature disease among physicians and lawyers. The mischievous system of severe competitive examinations in vogue in many communities is justly and unsparingly denounced as injurious both to teachers and scholars.

The connection between neurasthenia and lithæmia, which had been noticed by Murchison, Da Costa, and others, is acknowledged, and their frequent concurrence admitted. Dr. Mills considers, however, that they are by no means convertible terms. The connection between mental states and disease of the body is also dwelt upon, and among the diseases most likely to be developed by mental overwork he places phthisis, diabetes, and Bright's disease; finally the conclusion is deliberately expressed that many diseases not nervous in their seat or manifestation are developed directly or indirectly as the result of mental and nervous strain, through exhaustion, impairment, or lesion of the centres of the organic functions; in fact, overtaxing the mind and nervous system may be the exciting cause of almost any serious disorder to which chance, accident, imprudence, or infection exposes the individual.

This most important subject is ably presented by Dr. Mills, and in a manner which suggests an interesting topic for discussion. The pathology may be summed up in the statement that "in cases of mental overwork tissues fail to regenerate as fast as they break down." But may not the assimilative and regenerative powers be greatly reduced by accident or disease? Of course it is admitted that overwork is a purely relative term, and, while one would find his mental powers

severely taxed by a simple arithmetical problem, another will excite astonishment by his extraordinary capacity for mental labor. It would be of great interest and value to inquire into the precise condition of the brain underlying temporary differences of mental power, apart from the influence of education or habit, and aside from the native difference in brain-structure. Admitting the truth of the observation, it would be very profitable to study the exact conditions which make cerebration more facile and efficient at one time than at another.

It is well known that brain-workers sometimes can do a great deal, and at other times, when "not in the humor," they cannot write at all. Now, in what does this humor consist? Has it a physical basis? How is it affected by states of the brain or of the blood-supply? How is it affected by stimulants or by drugs?

Under the conditions of modern civilization, the question how to maintain the brain at its highest point of efficiency compatible with its normal nutrition is one of the most important that could be discussed. We think that its elucidation would powerfully influence public opinion as to the dangers of stimulants and narcotics, and might possibly tend to decrease greatly the consumption of alcohol and tobacco.

A NEW HOSPITAL WANTED.

IF, as the French say, nothing happened except the unforeseen, we should not be called upon to chronicle the disaster of the 12th instant, in which a wing of the Insane Department at Blockley was destroyed by fire and at least twenty of the unhappy inmates were suffered to perish miserably. It does not often happen that a prophecy is so promptly fulfilled as that contained in our last issue, in which the warning was given that the Kankakee horror might be repeated at our very door if prompt action were not taken to guard against it.

The report of Drs. Wood, Mitchell, and Mills, of the consulting medical staff of the Hospital, to the Board of Guardians, pointing out some of the glaring defects in construction and administration in this department, was indeed timely, and they are to be congratulated upon having done their duty. It is true that one of the city fathers has originated the striking idea that the publication of their letter to the Board, showing the unprepared condition of the hospital for just such an accident as occurred, was the indirect cause of it by inciting some weak-minded inmate to set fire to the building. Although this hypothesis, considered as an explanation of the accident, might satisfy the mind of a political partisan, it by no means furnishes a reason for the disgraceful state of affairs that made such an occurrence possible. It should be said, to the credit of the medical attendants and Miss Fisher's trained nurses, that by their exertions the disaster was much less fatal than it might have been.

The fact is that Philadelphia needs a new hospital and a new almshouse. There is no good reason at present for associating these institutions, but, on the contrary, many reasons in favor of keeping them as separate and as distinct as possible.

The present is a good time to move in this matter, while public attention is still directed to it. The various medical societies should as soon as possible adopt resolutions calling attention to the needs of the sick poor, asking that the Philadelphia Hospital be torn down and rebuilt in a style more worthy of the city whose name it bears, and requesting the removal of the insane department and the almshouse to a location some miles away from the heart of the city. The exigency is so imperative as to warrant calling a public mass-meeting to memorialize Councils upon the subject, and in this matter physicians should take an active and prominent part.

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

AN attempt will be made at giving a *résumé* of what is going on of practical importance, at present, in the hospital clinics and the colleges of medicine here.

After-Treatment of Breast-Amputations.—The immediate union, or by "first intention," is not admitted to be the best way of attempting to dress these wounds by many of the Paris surgeons. Here, as elsewhere, they are divided into two camps. M. Mouchez has lately given an account of eleven cases of removal of breast tumors. Several of them were very serious cases, but all of them were united at once under the antiseptic system and healed by first intention. M. Mouchez is of the opinion that a return of the tumor is often prevented by immediate union, or at least that a longer delay is procured in this way than by the old system. M. Verneuil, speaking at the Surgical Society, said, "For my part, I am opposed to any attempt at uniting breast-wounds at once. Unless they are slight ones, made for very small benign tumors, the immediate reunion of the parts presents grave dangers, and I am sure that many surgeons will agree with me in this matter. It is always very difficult to unite them, and this very fact is a strong argument against doing so. Many of these operations, properly performed, leave a wound of at least twelve to fifteen centimetres wide, which is almost, if not quite, impossible to join. This being so, those who wish to have an immediate reunion are forced to do what I call very parsimonious operations, and such attempts will do more than anything else to bring about a return of the tumor. I only want the record of my operations at La Pitié Hospital to show you that these wounds are not at all best treated by an attempt at union by first intention. In my last thirty-five operations I had only one death, which was that of a woman who had a cancer that had its seat in a deep organ. In all of these cases I had no erysipelas or any other complication, except in one case, which was that of a young woman upon whom I operated for a small adenoma; and, as the incision was slight, I thought I was justified in closing at once, but with bad effects, for erysipelas came on. I prefer even to exaggerate my tendency to leave these wounds open rather than to attempt to reunite them at once. It may be said that the cure takes a long time. What are the facts? My results are these: When I am forced to clean out the axillary space, it takes two months in all to get a perfect cure; but the most of my patients get up after fifteen days, and at the end of three weeks they return home to finish their cure. Now, what do we see with immediate reunion? It takes them at least three weeks to heal, and when it succeeds it almost always leaves a point open which takes a long time to cure."

M. Desprès followed in the same strain, and stated that it was only a deception of the eye to see these wounds heal up, for most of them left a fistulous opening that was very difficult to heal and predisposed to erysipelas. He said he dressed them open with a little lint and simple cerate.

M. Polaillon said he was a partisan of immediate reunion if the lips of the wound could be made to meet. He uses Lister's dressing.

M. Le Dentu was in favor of a mixed system of reuniting a part of the wound and leaving the rest open.

M. Trélat. "I am not an eclectic, but I have a system in this matter of primitive reunion. I have always practised it and defended it. It is a rule that I do not depart from if I can help it, but the possibility of doing it will vary according to circumstances. Asepsis is indispensable to success, more so than antisepsis, and I hold that reunion by first intention or an attempt at it is dangerous in the hands of those surgeons who have not been well schooled in the delicate manipulations of asepsis and antisepsis.

"With regard to relapse, I do not believe it will be different in one or the other mode of dressing, if the operation has been complete, which it can be in either system. Differing from M. Verneuil, I commenced by treating tumors of the breast by an open dressing, but since the introduction of the antiseptic methods I have reunited the lips of my wounds at once and whenever possible. If Velpeau and Nélaton did not succeed, it was because they did not take the same precaution that we do,—to leave a drainage-tube, that puts all danger aside of closing a wound."

M. Verneuil said, "I affirm again what I said before: that if these tumors are taken out, as they should be, by removing a large band of the skin and the aponeurosis of the pectoralis major, and even a part of that muscle, it will be almost impossible to make an immediate reunion."

M. Champonnière, in advocating closure of the wound, said, "We make very wide cuts and take out as much as do the partisans of the open system, but that does not prevent reunion unless the tumor has passed from the breast and invaded the skin for some distance beyond. For four years I have always made an attempt to reunite, and when I fail I am no worse off than those who prefer the open dressing."

Treatment of Intestinal Occlusion by the Galvanic Current.—Dr. Boudet has just presented to the Academy of Medicine a new apparatus which he claims can be used by any physician, even should he not be accustomed to the use of electrical applications. By its use, out of sixty-one cases it only failed seventeen times. Of these seventeen, eight were

operated upon by good surgeons, with the result that only two survived. This leaves forty-four cases in which this electrical application was successful, or seventy-two per cent. of all the cases,—a very good showing. The only contra-indication is cardiac asthenia. The apparatus is described as follows:

The intestinal rheophore is composed of a large gum sound, which is to be introduced into the rectum as far up as possible. This sound is armed inside with a metallic hood, that does not pass beyond the eye of the sound. The mandrin, or hood, is connected by a wire to one of the poles of the battery, and it and the sound are connected by means of a rubber tube with a small pump full of salt water. The warm salt water is made to pass through the sound, and at the same time it is charged by the metallic mandrin inside the sound, so that the water passes into the intestine, carrying the electricity to all parts of the mucous membrane. By this plan the danger of direct chemical action is averted, as the extremity of the metallic point does not pass beyond the rubber sound, and is thus isolated. The other pole of the battery is a large plate of metal covered with chamois leather, which is to be applied to the dorsal or abdominal region according to the case. The intensity of the current varies from ten to fifty milliampères, and the duration of its application should be from five to twenty minutes.

Doundakine.—M. Bochefontaine, of the Physiological Laboratory at the Hôtel-Dieu Hospital, is one of our most energetic workers. It was he that swallowed a pill composed of cholera microbes during the late epidemic, to prove that they did not cause the disease. He has lately been experimenting on this drug, the Doundakine, or Doundaké. It is furnished by the *Sarcocephalus esculentus*, one of the Rubiaceæ family, and is grown in great profusion along the African coast from Senegambia to Gaboon. It is an astringent and a real febrifuge, claimed to be equal to cinchona bark. No alkaloid has yet been extracted from it.

Kairine and Antipyrine.—A recent article has brought these medicines into prominence, and now there is great inquiry about them: they are both powerfully antipyretic.

When either quinine or cinchonine is heated with caustic potash, it gives off a vapor which when condensed produces an oily alkaline liquid that has been called quinoleine. The Germans have obtained a number of derivatives of this substance; among them are kairine and antipyrine; they are both soluble in water. Kairine is given in doses from 0.30 to 50 centigr. every hour; the antipyrine is employed in solution:

Antipyrine,	25	grammes.
Alcohol at 90°,	50	"
Syrup orange-peel,	200	"
Distilled water,	125	" M.

Dose of the solution, 3 to 7 grammes, taken at one hour's interval, in the afternoon, when the fever comes on.

These doses make the temperature fall from one-half to two degrees centigrade, and it will often fall to the normal, but rises after two hours' time. Antipyrine causes abundant perspiration and a feeling of well-being; there seems to be no accumulation, and the medicine can be continued for weeks at a time (for five weeks it has been given): it is usually very well supported, but sometimes causes vomiting. There is no injurious action on the nervous system. Both of these remedies are employed in all fevers, in tuberculosis, septicæmia, pyæmia, etc.

Antipyrine was discovered by Knorr in Germany, who sold the right to manufacture it to a firm called Meister Bruning & Co. They in turn sold the right for France to a company who were preparing to make it here. According to the French law, however, no medicine can be patented; but still a process of manufacture can be patented, so the company are trying that dodge, with several prominent doctors here against them. It is hoped that it will be declared free here, when all the great houses will make it, and after a more extended trial we can see if it really has the wonderful powers attributed to it.

While on this subject, it may be interesting to give some of the remedies that were presented this year for the cure of diphtheria.

Diphtheria.—Most of your readers are no doubt aware of the great prize called "*Prix de Saint-Paul*" here, which offers twenty-five thousand francs, or about five thousand dollars, for any remedy that will cure this disease. The following are some of the more serious remedies offered this year:

Quinoleine.

Sulphate of quinine in large doses, three to four grammes a day.

Acid salicylic and alum as a gargle.

Heavy petroleum oil.

Combustion of a mixture of turpentine and gas-tar, to be burned in the room.

Salicine.

There were also the usual number of witches' and other crazy people's cures.

Treatment of Sciatica by Refrigeration.—Dr. Debove has been obtaining excellent results by spraying ether all along the course of the nerve.

Tuberculosis.—Prof. Potain employs the following:

Chloride of sodium,	10	grammes.
Bromide of sodium,	5	"
Iodide of potassium,	1	"
Distilled water,	100	" M.

Sig.—A tablespoonful (15 Gr.) every morning in a glass of milk.

Palpitation of the Heart.—Prof. Potain, of Necker Hospital, recently reported a case of a woman 35 years of age, who had entered for violent palpitations of the heart. This

symptom, he said, seemed to him to be hardly ever a sign of real heart-disease, so much so that it had been said that when "a person complained of palpitation, look for the cause almost anywhere but the heart." This is perhaps bad advice, but it must be admitted as incontestably true that a large number of these patients have nothing the matter with the heart. Nervous palpitation comes from a variety of causes. It is enough almost to say that our patient is a weak, nervous woman, to know that she is particularly impressionable to nervous palpitations; but you must not think that it is a malady special to women, because it is frequent in men. It is true that men are less nervous than women, but when a man is nervous it nearly always manifests itself in palpitations of the heart, real or imagined.

"It is a long time since I have stopped counting the number of young men who have been brought to me for heart-disease between the ages of 17 to 20, before they have done their military service, who afterwards made as good soldiers as any. In these cases the palpitations are simply the result of rapid growth, a sort of hypertrophy of adolescence, which a little convallamarine or iodide of potassium will soon set right.

"We also see these palpitations in middle-aged men who are very nervous: we call them hypochondriacs. Anæmia is also a cause. Among the palpitations of this order can be ranged those that are consequent on certain intoxications, as the exaggerated use of tea and coffee,—very common among the spinsters of old England, who indulge in too much tea. Then there is tobacco. No doubt it will be said that plenty of excessive smokers do not have palpitations; but that does not prove that nicotine will not produce them in persons who are predisposed to such a weakness. In some people who badly digest certain kinds of food, it is enough to produce an attack of palpitation of the heart after eating them; others will have it from certain wines or liquors. Hepatic disease will produce it. In phthisis it is not at all rare. It has been said, When a patient comes to you complaining of palpitation, examine his lungs; when he complains of shortness of breath, then examine his heart. This is an exaggeration, without doubt; but you will be surprised to find how much truth there is in it. Women with uterine troubles will often have palpitations.

"All these different causes will have to be thought of; then try repose, and see if the symptoms are simply nervous or not. There is also a good means of diagnosis in digitalis, for its administration will be without any appreciable action if the palpitations are simply nervous; but if they are kept up or exaggerated by any organic lesion, no matter how small, you will see the characteristic effect of digitalis."

"*Bruits Extra-Cardiaques.*"—At a late clinic, Prof. Potain, in referring to these outside cardiac murmurs, spoke as follows: "A large number of observers have remarked these murmurs in persons in whom no lesions of the orifices could be detected, and they have given many reasons for their cause and nature. Laennec gave an opinion that they resulted from a spasm of the cardiac muscular substance. It has been asserted that these same 'bruits' are the result of an irregular vibration of the folds of the valves, but this is an hypothesis that is not founded on fact or sound reasoning. Again, these murmurs have been considered as resulting from a mitral insufficiency that is purely functional; but the authors of this last theory give no reasons for it. Parrot said that they arose from the insufficiency of the right auriculo-ventricular valve. Laennec remarked that on making these patients suspend their respiration the murmur would stop, while real cardiac ones would continue; but this is very uncertain, and in the greater number of patients it will fail.

"I have studied these cases with great care, and think I can say that these murmurs are to be found very often, as a large number are seen yearly in this hospital. They arise from a rapid inspiration of a certain quantity of air in that part of the lung that is situated between the cavity of the thorax and the ventricle. At the moment of the ventricular contraction a sudden separation of the side of the heart and the walls of the thorax takes place, the lung is drawn into the vacant space made, thus increasing its size; the inspired air that follows this increase in volume is the cause of this '*bruit de souffle.*'"

Treatment of Porrigo, or Eczema Capitis.—Dr. Descroizilles, speaking at the Hôpital des Enfants, said, "This scurf or scall, called popularly '*gourmes*' in children, is quite common, and it will be of practical use to you if I give you our mode of treating it, with a few words of advice. The old pathologists did not admit of treating it at all, and they considered that if you removed the scurf and got rid of the crusts you would bring on all kinds of trouble, including most formidable cerebral affections. But we moderns have not adopted these views; perhaps we have put them aside too much, for one often does see some intercurrent malady appear with the disappearance of the scurf. I believe it is reasonable to take into account the common belief that there is danger in removing these crusts: so I advise you to adopt the wise precepts of Rilliet and Barthez, who said, 'Do not attempt to destroy this scurf when you find that any trouble follows any diminution of the morbid secretion, or if the general health of the child improves as the eruption progresses.' You must also abstain from action if the cutaneous affection has come on after an ophthalmia, or if any eye-trouble follows after the treatment for

removal has commenced. If the porrigo occupies a great extent, do not attack it all at once, but try a part. As a last precept, 'go slow!' in all circumstances.

"The treatment is mostly with emollients or weak astringents, or applications of rice or starch-powder, subnitrate of bismuth, or oxide of zinc, with olive oil. When the concretions have fallen, good effects are obtained with pomades of vaseline, to which may be added tar, tannin, or calomel, one-twentieth part. Sometimes you may try oil of cade, cod-liver oil, or some of the sulphur preparations, looking at the same time to the general health of the young subject.

"But it is by swathing the parts with a rubber cloth that you will do the most good, taking care to take off the envelope as often as twice a day and wash it with a solution of oak-leaves in water. The bandage must not compress the parts, but fit loosely. On the head a cap can be fitted, but it must not fit tightly. The face may have a loose mask. The part affected we wash with an astringent liquid, and the apparatus is kept on night and day. Thus separated from the air and submitted to a uniform temperature, the skin will clean itself promptly usually in seven days."

Cocaine.—The papers and the clinics are wild over this new local anæsthetic, or, as De Wecker calls it, "paralyzer," for he claims that it is on the extreme ramifications of the nerves that it acts. Panas, Landolt, and all the ophthalmologists are actively experimenting with it. Even the dentists have their say, to the effect that they destroy the dental pulp with it, and by its use operate without pain on cavities that are or were exquisitely sensitive. The druggists are also active, and are making all sorts of "pastilles" that they announce as sure cures for all troubles of the larynx, gastralgia, and nervous vomiting. At a meeting of the Paris Société de Chirurgie on December 31, M. Cazin stated that he had used it in a case of vaginitis in which, for that cause, the patient had been unable to have sexual connection for years. The application of a solution of cocaine on the vulva and in the vagina was sufficient to make the hyperæsthesia of the region disappear during the time necessary for coition.

We have now plenty of hydrobromate of cocaine made by a French house.

Dr. Doleris, who has charge of the "*Maison d'Accouchement*," has just told us of some of his experiments with the drug. He has been able to suppress entirely the pain accompanying the dilatation of the cervix, also at the moment of the expulsion of the fœtus, during the last period of confinement, He also obtained a very notable decrease in those perineal pains that are so severe for many women, and without interfering with the normal birth of the child.

M. Paul Bert has also been making some little experiments, and he finds in vesication that all that was needed to entirely suppress the pain was to make an injection into the sac and to cover it with a cloth imbibed with the cocaine. He remarked that the insensibility was not uniform; that it presented itself in the form of little islands, with a sensitive interval between them. It would seem, then, true that it acts on the terminal points of the nerves.

M. Regnard placed a fish in a solution of cocaine, and in a few minutes it seemed to cease to breathe; but it was only a suspension of respiration, as the quantity of oxygen in the water did not vary, and the production of carbonic acid was not noticed. At the end of two hours the fish was put into fresh water and revived.

The new French Surgical Congress, we are informed by Dr. Pozzi, the eminent surgeon of the Lourcine Hospital, will hold its first session in the early part of April, at the Medical School, which will then be vacant for the Easter holidays. Some very interesting subjects will be treated, such as

"What are the Best Means for curing Cold Abscesses?"

"What Indications will the Examination of Urine furnish to Surgical Practice?"

"What are the Best Dressings to Employ in the Army when in the Field?"

"What are the Indications for Operation in Deep Wounds of the Abdomen?"

"The Origin and Nature of Coxalgia."

"Indications for Trepanning in Traumatic Lesions," etc., etc.

A very curious study is being made of the cause of the very high rate of mortality in children in France, which is estimated to have been for some years as high as one hundred thousand a year in all France, or say ten millions in the last hundred years. It is in great part caused by the habit of the French women of all classes in the cities sending their children out into the country to nurse. It is astonishing to strangers in Paris and the large French cities to see so few young children in the streets. For a number of reasons, very few children are brought up in Paris. First is the want of space; then the fact that proprietors of many apartments will not rent them to people who have children. Moreover, it has been the custom for years to send the children out to nurse, and so the "baby-farming" system flourishes here more than anywhere, and is probably principally responsible for the above frightful mortality.

Dr. Germain Sée and Prof. Hardy are having it tooth and nail over the treatment of pneumonia. Dr. Sée claims to have found the bacillus of pneumonia, and calls this form of it "*pneumonie parasitaire.*" His treatment is expectant, and he discards bleeding and all depressing medicines like antimony tartrate. Sée is now giving a series of lectures on asthma, in which he defines as a trinity asthma, emphysema, and chronic catarrh.

The following is a list of the principal recent papers and works of some of the most prominent French doctors, and it will show their present line of thought:

Sappey.—"Effects of the Experimental Lesion of Peduncles of the Brain."

Ball.—"Prolonged Dreams."

Dujardin-Beaumetz.—"Intestinal Antiseptic Medication."

Hardy.—"Broncho-Pneumonia and Commencing Tuberculosis."

Tripier.—"Deviations of Cardiac Rhythm associated with Epilepsy."

Vulpian.—"Tabes Dorsalis."

Trélat.—"On the Value of Plastic Operations of the Palate, and the Age when they should be attempted."

Doleris.—"Embryotomy with the Hook and Cord. Recommended by Dr. Pajot."

Terrier.—"Clinical Remarks on a Third Series of Twenty-five Ovariotomies."

Guéneau de Mussy.—"Study of the Hygiene of Moses and the Ancient Israelites."

Germain Sée.—"*Pneumonie parasitaire*, Acute Bronchitis, Gangrene, Cancer, and Hydatids of the Lungs."

Fournier.—"Lessons on Tabes of Syphilitic Origin."

Jaccoud.—"Medical Lessons at La Pitié Hospital."

Galezowski.—"Diagnosis and Treatment of Ocular Affections."

Gosselin.—"Letter on the Treatment of Hæmatocele."

Panas.—"Local Anæsthesia of the Eye with Cocaine."

Gallard.—"Clinical Lessons on Menstruation and its Troubles."

Siredey.—"On the Diagnosis of Typhoid Fever in the First Stage."

Auvard.—"Corrosive Sublimate in Obstetrics."

Medical Study in Paris.—A few words on the opportunity for observation and study in Paris may not come amiss. While there is a good deal of feeling among French students against foreigners, which they lately showed by a long series of letters to the papers and in signing petitions to the Minister of Public Instruction, still the professors and all the hospital doctors are very courteous, and they willingly show a stranger all over their wards and explain all the cases. The students seemed incensed particularly at the ease with which up to the present quite a large number of women who are of Russian nationality have obtained permission to enter the Medical School without first obtaining the French degrees of Bachelor of Arts and Sciences, as they (the French) are compelled to do. This has been accorded to most foreigners, but is now refused to many unless they can show diplomas of study equal to those of the French students. The women, too, had applied to be admitted as *internes* to the hospitals, where they are already allowed as *externes;* but this is strenuously opposed. All this does not amount to much except to those who may wish to obtain the French diploma, which will now not be given unless the candidate passes all the examinations, eleven in all, commencing with botany, zoology, and chemistry, and going all through the other branches, with two practical proofs of operative ability on the cadaver, one of dissection and the other of amputation. This is the difficult side of it now. For the nice side of Paris study, any one who has a wish to study here can have more for nothing in the way of practical medicine and surgery than anywhere else in the world.

There are over twenty hospitals in which every morning you can enter without fee of any kind, and follow the doctor from bed to bed, and see the patients, examine them, and hear his treatment. This from 8 to 10 A.M. Then at 10 you may attend a clinic, either medical or surgical, and see the best professors perform operations. You may then go into the consulting-rooms and see the treatment given to those poor people who attend them; all this without fees. This will take all the morning. Then in the afternoon you may go to the Medical School and attend all the lectures without any charge. All are welcome who choose to enter. Should you wish to attend any of the practical laboratories of chemistry, physics, pathological anatomy, etc., or dissections, the fee is eight dollars for the year. The new dissection-rooms in Paris consist of eight large buildings that have just been built and opened this winter. They have been built of white stone, are very lofty, and "material" is plenty, some two hundred cadavers on the tables all the time. This course is from 12 noon to 4 P.M., a lecture being given from 12 to 1, or 1 to 2, in each building, by one of the eight "Prosectors." Eight dollars, or forty francs, will admit any doctor to all this. In regard to obstetrics, there is at least *one birth daily* at the Faculty's "*Maison d'Accouchement*," at which you may "assist" gratis. This also occurs in three of the hospitals. There are quite a number of outside lessons (private), given by the younger professors for about twenty to thirty dollars a course. A knowledge of French is of great importance to take advantage properly of all that is given away; but at the same time one who only wants to see and make his own diagnosis can visit a few hundred different kinds of "*malades*" every day and see the operations done without any charge. This is spoiled a little by the fact that living is dear in Paris. Even in the "Latin Quarter" you will not be able to live, and poorly at that, under ten to fifteen dollars a week. The lowest board per month is forty dollars.

The actual number of students entered on the books at the medical school here is four thousand, of whom five hundred and thirty-

eight are foreigners, mostly Russians, Poles, Roumanians, and Serbs, and a few Spaniards and South Americans; only two or three English and Americans (United States). The number of women admitted this year is seventy-eight, of whom only thirteen are French, the rest mostly Russians and Poles, one American. No difference is made between the male and female students. You will see two women and three men often assigned to dissect one male or female subject, just as it happens. One can also see a woman do a post-mortem on a male subject. The women-students are assigned to and visit the male wards, and "assist" at all the operations, including catheterization.

J. Linn, M.D.

Paris, January 24, 1885.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

A STATED meeting was held January 26, 1885, Daniel Lewis, M.D., President, in the chair.

AFFECTIONS OF THE EAR INFLUENCED BY OR DEPENDENT ON MALARIA AND DEFECTIVE DRAINAGE.

Dr. O. D. Pomeroy read a paper with this title, and said that the question was one which was beset with difficulties, the chief difficulty being to determine to what extent the symptoms might be due to malaria or to quinine. He quoted extensively from authors who had reported cases of ear-disease of supposed malarial origin, including the names of Weber Liel, Hotz, Voltolini, and others. In some of the cases bad house-drainage evidently played an important rôle in the etiology or continuation of the disease. The symptoms usually consisted of chills and fever of an intermittent type, of tinnitus aurium, etc. Weber Liel said that in the treatment quinine alone in large doses gave relief, and the earlier it was prescribed the more thorough and rapid would be its action. A change of air had effected a cure in some instances when all other means had failed. Dr. Pomeroy related the case of a man whom he saw at the Manhattan Eye and Ear Hospital, in 1883, who had lived in a malarious district, and whose ear-symptoms improved under the administration of quinine, although the discharge from the meatus did not cease until after local applications of a solution of nitrate of silver.

In order to determine as far as possible the influence of malaria in the production of ear-affections, he had sent interrogatories to thirty-six different aural surgeons in the United States and Canada, to which he had received replies from twenty-eight, including the names of Miller, Blake, Seely, Theobald, Burnett, Holmes, Jones, etc. Most of these gentlemen did not give credence to the belief that ear-diseases might be directly dependent upon malarial poisoning, although not a few had seen cases in which the aural affections were aggravated by malaria or bad drainage.

In conclusion, Dr. Pomeroy expressed the opinion that malaria and bad hygienic surroundings, including defective house-drainage, exerted a modifying influence on ear-affections, but he could not accept the view expressed by Weber Liel, Hotz, and Voltolini, who described cases of ear-disease caused by malaria.

DISCUSSION.

Dr. Hackley opened the discussion, and said he thought we might perhaps have gained some information from the homœopaths with regard to the influence of malaria upon ear-affections unmodified by the effects of quinine, for cases treated by their methods, it was supposed, ran a more natural course. He himself was in the habit of administering quinine in cases in which ear-disease was complicated by malaria. As to the occurrence of aural troubles from malarial poisoning, he supposed it would probably depend indirectly upon different states: first, upon pharyngeal trouble extending to the Eustachian tubes; second, upon so-called vaso-motor disturbances; and, probably, upon affections of the internal organ of hearing arising through changes in the vaso-motor condition. But quinine and malaria were so badly mixed up in the cases of ear-trouble which he had seen that might have a bearing upon the question under consideration, that he was unable to say which had exerted the more important influence.

Dr. Simon Baruch would enter a protest against the increasing tendency to attribute all simple, as well as complicated, pathological conditions to malaria as the chief etiological factor. That there were any cases of malarial ear-disease he regarded as extremely problematical. He had resided in a malarial district for twenty-five years, and never before had he heard of ear-disease being attributed to malarial poisoning. He felt sure that in the cases whose histories were read by the author of the paper there must have been some hidden error. Although many diseases had been ascribed to malaria, standard authorities had failed to recognize any of the pseudo-malarial affections as due to malaria, and in this way they had refused to shield those careless diagnosticians who took malaria as a text for every slip in their diagnosis. He quoted from the statistics of the Board of Health of New York, showing that a much larger proportion of deaths from malaria were reported than would be recognized by any authority. There must therefore have been a large number of errors in diagnosis.

Because benefit had been derived from quinine in certain cases of ear-trouble it did not prove that they were due to malaria. In reviewing the cases reported by Weber Liel, Hotz, Voltolini, Pomeroy, and others, he thought he could find very positive evidence that the cause of the ear-affection was not malaria, although malaria coexisted in some of the cases.

Dr. JOHN C. PETERS had had several attacks of fever and ague years ago, and in the first attack, when he was taking no quinine at all, the most troublesome symptom was tinnitus aurium. He also referred to the case of a lady in whom the ear-trouble was evidently due to bad house-drainage, and recovery took place after the administration of quinine. Dr. Baruch had said that cases of malaria were reported in New York in midwinter, and cast doubt upon the diagnosis because the best authorities had stated that it could not exist when the temperature fell below a certain point. Dr. Peters would call attention to the fact that water and bad drainage existed under many of the houses and streets in New York during the entire year, and consequently, if the houses were kept warm, malaria was liable to develop. There were not a few cases of mixed malaria; that is, of disease due to the combined influence of bad drainage and malaria. He thought that after Dr. Baruch shall have lived in New York as long as had some of the older residents at the present day, he would be less sceptical with regard to the large number of cases of malaria in this city.

Dr. HOLCOMBE did not know that he had, during over twenty-five years' experience in ear-diseases, ever seen a case in which the aural affection could be attributed directly to malaria. He thought malarial and aural affections happening in the same patient at the same time might be misleading, especially if we were disposed to accept the view that there were really cases of malarial otitis. He remembered that once, in conversation with Ricord, the latter was asked if he had ever known a case of syphilis to be cured. He replied that he had now been in practice about fifty years, and, while he could not say whether any of his cases had really been cured, he hoped to live long enough to be able to answer the question positively. So it was in malaria and ear-affections. The patients might have relapses, and it was difficult to say just how much the aural trouble might be due to malaria or bad drainage.

Dr. POMEROY, in closing the discussion, said he had been very careful not to bring theory into the consideration of the question. He had all the time been in the position of the investigator having but one interrogation-point before him, and that was, What is the truth? He had refrained from expressing an opinion. He thought he had wisely put into the title of his paper, "due to malaria or bad drainage," and not alone "to malaria;" and we were able to dodge around a good deal with that amount of latitude. It might be said that in many of the cases quoted there was a history of dampness about the dwellings, and there was an active cause of catarrh, and catarrhs with reduced health favored ear-affections. He did not believe that malaria would ever be put down as the direct cause of typical otitis. We might say, however, that inflammatory affections of the ear might be aggravated, in an indirect way perhaps, by malaria and sewer-gas. We might certainly say that painful affections of the ear were often aggravated, sometimes perhaps almost excited, by malaria and sewer-gas influences. But the question was a mixed one, and it seemed impossible thoroughly to unravel it.

THE MANURE NUISANCE.

Dr. A. HADDEN, of the Committee on Hygiene, reported concerning the manure-dumps along the East River front. Formerly the odor given off by these piles of decaying manure filled the atmosphere for more than a mile around. The question had arisen in the minds of many whether they were truly nuisances and detrimental to the health. Professors Chandler, Doremus, Draper, and others, had said the air was unhealthy to inspire, and the committee thought it was beyond a doubt but what they rendered the neighborhood insalubrious, although they hesitated to commit themselves to the belief that they might give rise to any specific form of disease. The manure was now being removed as fast as the present methods would permit.

Another nuisance was the periodical removal of the manure from the pit at the stable, which rendered the atmosphere of the neighborhood offensive. Several plans had been suggested for lessening the nuisance: one was to wash the material and use the straw for making paper; a second, to destroy it by rapid combustion; and a third, to compress it within barrels at the stables. The latter method seemed to the committee the most practical, and it had been adopted by certain of the stables in the city with excellent results. The manure so packed remained odorless and not detrimental to the health for a very considerable period of time. The method was by no means new, having been advocated by the public press years ago.

The conclusions at which the committee had arrived were, that the manure-dumps of this city were nuisances and highly detrimental to the public health, and all reasonable means should be used to entirely do away with them, and they recommended to the Society to insist upon the health officers adopting some feasible method, whether those suggested or others, to lessen the nuisance or to entirely do away with it.

Dr. JOHN C. PETERS said he had paid a visit to the manure-dumps that day, and the smell which he encountered was something to be remembered. What added to the offensiveness of the atmosphere was a sewer which carried the refuse of slaughter-houses, a fat-rendering establishment, besides other filth. It might be added, he said, that one of the largest oleomargarine-manufactories in the city was situated in close proximity to the mouth of this sewer, and received the full benefit of its sweet perfumes.

The report of the committee was accepted.

The ability of members, who proposed to continue to practise medicine, to resign from the county societies was doubted, and a motion was adopted requiring the *comitia minora* to report whether the law of 1880 repealed that of 1828, by which all legal practitioners had to be members of the county societies.

NEW YORK ACADEMY OF MEDICINE.

STATED meeting, February 5, 1885. The meeting was called to order by the retiring President, FORDYCE BARKER, M.D., LL.D., who introduced the following-named gentlemen occupying seats upon the platform: Dr. Parvin and Dr. S. Weir Mitchell, of Philadelphia; Dr. Shutuck and Dr. Chadwick, of Boston; Dr. Billings, of the U. S. Army; and ex-president Dr. Anderson.

On motion of Dr. C. R. AGNEW, an invitation was extended to Prof. Merriam, of the Columbia College, to lecture before the Academy, on the "Temple of Æsculapius."

Dr. BARKER then read his

RETIRING ADDRESS,

in which he said he would briefly recall the more prominent features in the history of the Academy during the period of his connection with it as presiding officer, and would make some suggestions relating to its future growth.

Since his connection with the Academy it had acquired a new and commodious hall, largely through the munificent donation of Dr. Abraham DuBois. But they were fast outgrowing this hall, as the library was nearly full, and had gained since 1879 about twenty thousand bound volumes and six thousand pamphlets. The circulating department contains about six thousand volumes. In the journal-room are between two and three hundred medical journals in all languages in which there is to be found a medical literature. The Academy was greatly indebted to Messrs. Wood & Co. and Messrs. Appleton & Co. for large donations of their new publications, and he suggested that it would be profitable for both authors and publishers to give to the Academy a volume of each of their new works.

The Academy had absorbed another very important organization,—The Medical Journal Association. He briefly alluded to the fact that nearly two years ago the Academy passed through the segment of a cyclone, and yet during the past year it had approached more nearly its avowed aims and high purposes than during any former year since it was founded. Four times as many papers had been offered as there were sessions at which to read them. The discussions on the papers had been chiefly by those familiar with the subject and specially prepared to make remarks, and thus the time of those present at the meeting was not wearily wasted in listening to crude, profitless, and digressive talk.

It was thought that the mortgage on the Academy of five thousand dollars would soon be raised. The Sections of the Society, with the exception of that on Obstetrics and Diseases of Women and Children, had not, it was to be regretted, done any scientific work. He hoped the time would soon come when the Academy could offer a home, free from expense, to such societies as the County Medical, the Pathological, etc.

The standing committees, with the exception of that on Medical Education, had faithfully discharged their duties. He thought the time was now ripe for the Committee on Medical Education to do important work towards the elevation of the standard of medical education. In this connection he referred to the subject of a State board of medical examiners, and asked if the demands of the most progressive members of the profession would not be satisfied if the Committee on Education of the Academy of Medicine were made a supervisory board of examiners for the medical colleges of this city. He then said that none but those who were well acquainted with the facts could appreciate the great advance which the medical colleges of New York had made during the past quarter of a century in teaching and in their facilities for imparting a thorough education in all departments of medicine. He also alluded in terms of highest praise to the good work done by the polyclinics of the city.

Dr. Barker then said that what the Academy requires in the future is a large fire-proof building, including room for a complete medical library, a large hall for its meetings, and others for smaller societies; a large room for a museum illustrating physiological and pathological anthropology, which should include a craniological series, a pathological series, and a series of sections and dissections, illustrating both topographical human anatomy and a comparative anatomical series; an anthropometric laboratory provided with the best means of measuring human bodies, the faculties, and everything cognate to these subjects, which should include a set of psychometrical instruments and everything pertaining to the series; a lecture-hall equipped with apparatus for lectures and demonstra-

tions of all kinds; a thoroughly-educated and trained pathologist, a capable mechanic, and a practical phonographer.

Although this was a broad scheme, the munificent gifts made to medical institutions recently by various wealthy persons gave reasons for hoping that it would be carried out.

ADDRESS OF DR. JACOBI.

Dr. ABRAM JACOBI, the newly-elected President, then took the chair and read an address, in which, after expressing his appreciation of the high honor conferred upon him and making remarks complimentary to the retiring President, he directed attention to some means by which the interests of the Academy might be promoted.

He thought it desirable that, instead of but one or two, all the Sections should begin to put forth some signs of active life. He also thought it desirable that the several medical societies of the city should meet in the halls of the Academy. It was hoped that the older members would not give up their duty in the Academy, thinking that the younger ones should take on their work. They should remember that the young man with wisdom and learning was often anxious to listen to the advanced in age, who had not only wisdom and learning, but also experience. He contrasted the means by which institutions like the Academy of Medicine in this country were supported with the means of support of similar institutions in Europe. Here the man who devoted attention to promoting the advancement of medical learning and the public health by labors in institutions devoted to science had also to keep up an active practice of medicine, a fact which did not permit him to forget the aphorism that the end of all medicine was the promotion of the public health. The time would come, he hoped, when all sanitary laws would bear the evidence of a consultation by our legislators with the medical profession. The President of the Board of Health would in time be chosen by the better part of the profession; indeed, the most improbable of all things would perhaps come to pass,—viz., the public would come to recognize the fact that the government of hospitals was not complete without a medical adviser in their boards.

"Medicine during the Eighteenth Century" constituted the main body of the address, and in his remarks Dr. Jacobi gave France the honor of the first position, which, however, it had since lost, and at the present time Germany stood in advance of all other countries in scientific medicine. It had been said that America had not produced a John Hunter or a Virchow; but all England had produced only one John Hunter, and all Germany only one Virchow. America had, notwithstanding, many names to which she could refer with pride, and not a few of them were associated with the New York Academy of Medicine. It could be said of the American practitioner that he had received, appropriated, and digested the results of foreign scientific labor, to which he had added his own. The state of medicine during the eighteenth century was such as to favor the development of homœopathy and other species of charlatanry which flourished so vigorously during that period. Finally, a school of pathologists sprang up, and this department of medicine so occupied the minds of medical men in Germany that the public were in a position, about the time of Rokitansky, in which they preferred the homœopath's pill-box to the pathologist's post-mortem case.

The time was, or rather now is, when a new theory in pathology could change the entire basis of etiology. It was unnecessary for him to explain that he referred more particularly to bacteriology. In this connection he referred to the pathology of Virchow. It was not his intention to make the present occasion one for eulogizing that eminent man, but he would say he was of opinion that bacteriology had too often to beg the question. His reason for referring to the subject at present was to suggest that the Academy should do its share towards settling the vexed question of the part played by bacteria in the production of disease. It is time, at any rate, that incapable authorities should cease to occupy our time with their discoveries of germs which they claimed to be the sole cause of this, that, or the other disease, but which were only to be replaced by the next coccus that might come along. We were willing to listen to such gentlemen as Koch and his compeers, who could wait until their views and discoveries were matured before they gave expression to them, but fifty thousand beginners in the studies of the microscope, like fifty thousand beginners in playing the piano, might become a noisy nuisance. He then mentioned some of the points of resemblance between the symptoms of chemical poisoning and those of infectious diseases said to be due to a peculiar germ, and expressed the opinion that it had not been by any means definitely proven that any given bacteria were the real cause of particular diseases. He said that he had but recently learned that four years before Semmelweiss had proclaimed the contagious character of puerperal fever it had been taught by our own anatomist, philosopher, poet, and Autocrat, Oliver Wendell Holmes.

In accepting the loving cup from the retiring President, he said an invitation would at another time be extended to the Fellows to participate in its pleasures in a more commodious hall.

Dr. CHADWICK then read a letter, directed to Dr. Barker, from Dr. OLIVER WENDELL HOLMES, who had been invited to be present; after which the Society adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held January 28, 1885, JOHN A. WYETH, M.D., President, in the chair.

ALTERATIONS OF TEMPERATURE DUE TO CEREBRAL LESION.

In the discussion on some specimens presented for candidates for membership, Dr. Seguin inquired of Dr. Janeway whether he regarded the rule of Charcot, concerning the significance of the temperature after cerebral hemorrhage, as true in practice.

Dr. JANEWAY replied that patients upon whom he had sought to test the rule had recovered, and he had consequently been unable to determine whether the symptoms had been due to hemorrhage or some other lesion within the cranium.

Dr. SEGUIN had not doubted the practical value of Charcot's statement until recently he had a patient who became affected with hemiplegia and aphasia, and it was found the temperature at first was depressed and afterwards elevated. Diagnosis of cerebral hemorrhage was made. The patient improved, but subsequently had another attack which ended fatally. Much to his surprise, he found at the autopsy thrombosis of the middle cerebral artery due to syphilitic endarteritis, and no hemorrhage.

MYXO-SARCOMA OF THE THUMB.

Dr. T. MITCHELL PRUDDEN presented the thumb of a man about 65 years of age, which had been removed for myxo-sarcoma, which had developed after the member had been stung by a wasp.

SALIVARY CALCULUS OF STENO'S DUCT.

Dr. E. C. SEGUIN presented a specimen obtained from a gentleman who was under treatment for specific hemiplegia. He was now in good general health; but a few days ago, without any apparent cause, the cheek began to swell in front of the parotid gland, and there was also swelling to be seen about the orifice of Steno's duct, from which a profuse amount of mucous fluid escaped. The next morning the patient found the calculus presented lying between the cheek and jaw, and the duct was diminished in size. A few years ago Dr. Seguin met with a similar case of calculus of Wharton's duct in a lady of gouty diathesis. There was swelling and an abnormal tenderness, and on introducing the probe into Wharton's duct it came in contact with a hard substance. Within a few days the calculus was thrown out spontaneously as in the case just related. It seemed somewhat remarkable that there could be spontaneous extrusion of calculi of so large size.

DIAGNOSIS OF KIDNEY-DISEASE AND PLEURISY.

Dr. BEVERLY ROBINSON presented specimens, and related the history of a case, which illustrated certain points of interest The patient was 44 years of age, and entered St. Luke's Hospital November 26, 1884, having, three days after exposure to wet, been taken with a chill, followed by fever and severe pain upon the right side of the chest. The expectoration became tenacious, and at times was stained with blood. The urine was of a specific gravity of 1013, but was in other respects apparently normal. Over the right lung posteriorly, as high up as the spine of scapula, was bronchial respiration; over the upper portion of the lung were bronchial râles; inspiration was imperfect. Over the base was resonance, but just above it was absolute flatness. The respiratory murmur was exaggerated over the left lung. The patient died on the 28th. At the post-mortem old pleuritic adhesions existed over the right lung. Near the right base was about a pint of purulent fluid. There was chronic diffuse nephritis.

One point of interest in the case related to the apparently normal condition of the urine, with the exception of low specific gravity, while marked kidney-lesions existed. Dr. Robinson said that in his experience this was not of infrequent occurrence. He regarded low specific gravity of the urine continuing for some time as of great diagnostic importance as pointing to chronic renal trouble, and said that one should be suspicious, when it was present, of kidney-disease, although the microscopic or chemical tests were negative.

Another point of interest was the difficulty of differentiating between pneumonia and pleurisy. The text-books, he said, were in error when they laid down as a general rule that in considerable pleuritic effusion there was always diminution and loss of thoracic resonance, or diminution and loss of vocal fremitus. The present case he thought was an exception to that rule. There was increase of vocal resonance and vocal fremitus at the base of the right lung, notwithstanding there was a pint of fluid found post mortem. Within three weeks past a man entered St. Luke's Hospital with increased vocal resonance and fremitus and marked ægophony over the right base, and yet on introducing the hypodermic needle no fluid was found. It was not until the third tapping that he obtained fluid, and then he withdrew a quart. After withdrawal of the fluid there was even less vocal resonance and fremitus than existed before aspiration was performed.

How are such cases to be explained? In the first place, it had been shown that the sound-conducting power of fluids depended to some degree upon their nature, and in some cases, more particularly in those in which the effusion was considerable in quan-

tity and had formed rapidly, the thoracic walls became distended perhaps more in proportion to the compression of the lungs, and in his opinion under these circumstances the thoracic vibrations before the disease would not be so intense as after a certain amount of the effusion had become absorbed.
